Pain arising from the various viscera in the thoracic cavity and from the chest wall is often qualitatively similar and exhibits overlapping patterns of referral, localization, and quality, given the proximity of the various organs and the vagaries of perception of pain of visceral origin. This leads to difficulty in the differential diagnosis of chest pain (Table 31-1). Nevertheless, many chest pain syndromes are sufficiently distinctive clinically that diagnostic efforts often rely on accurate description of the characteristic pattern of pain. The importance of the medical history in unraveling the various causes of chest pain cannot be overemphasized. The locations to which various pain syndromes are referred in the chest are illustrated in Figure 31-1.

PLEUROPULMONARY DISORDERS

Although the lung parenchyma and visceral pleura are considered to be insensitive to ordinary noxious stimuli, immunohistochemical studies from vagal denervation and talc-pleurodesis animal models indicate the presence of nerve fibers in the visceral pleura that may be capable of conducting pain stimuli.^{25,26} Pain does arise from stimulation of the mucosa of the trachea and main bronchi.²⁵ The lungs and bronchi are innervated with mechanoreceptors that respond to stretch (inflation or deflation of the lungs) as well as chemoreceptors called J receptors that respond to a variety of pain-inducing chemicals, including bradykinin, prostaglandins, serotonin, and capsaicin.^{27,28} Inhalation of irritant substances, such as ammonia, can trigger a cough reflex and can produce a sense of rawness, tightness in the chest, and pain. In addition, rapidly adapting mechanoreceptors that respond to lung deflation are also "irritant receptors" and signal respiratory pain. J receptors have been proposed to contribute to discomfort and pain that accompanies breathlessness.²⁷⁻²⁹

These receptors are, in turn, innervated by vagal and spinal splanchnic afferent fibers. Nerve fibers that travel in the vagus nerves, including myelinated axons that carry impulses from slowly adapting stretch receptors in the conducting airways, myelinated axons that lead from rapidly adapting irritant cough receptors in the trachea and bronchi, and unmyelinated axons that subserve the extensive network of C fiber receptors (e.g., "pulmonary" J receptors and "bronchial" C fibers), are most important.³⁰

The pulmonary causes of chest pain may be related to the pleural tissue, pulmonary vessels, or lung parenchyma. Causes of chest pain related to the lung parenchyma include infection, cancer, or chronic diseases such as sarcoidosis. These are discussed in more detail elsewhere in the textbook.

Table 31-1 Common Causes of Chest Pain

PLEUROPULMONARY DISORDERS

Pleurisy
Infection
Pulmonary embolism
Spontaneous pneumothorax
Collagen vascular disease
Sickle cell disease
Familial Mediterranean fever
Malignancy (e.g., mesothelioma)
Pulmonary hypertension
Pulmonary embolism
Primary pulmonary hypertension
Eisenmenger syndrome

TRACHEOBRONCHITIS

Infection
Inhalation of irritants
Malignancy

INFLAMMATION OR TRAUMA OF THE CHEST WALL

Rib fracture
Muscle injury (myalgia)
Infection
Malignancy
Sickle cell disease
Neuritis-radiculitis
Herpes zoster infection

CARDIOVASCULAR DISORDERS

Angina pectoris
Variant angina
Myocardial infarction
Aortic valve disease
Mitral valve prolapse
Hypertrophic cardiomyopathy
Pericarditis
Cocaine toxicity

DISORDERS OF THE AORTA

Aortic dissection

GASTROINTESTINAL DISORDERS

Reflux esophagitis
Esophageal motility disorders
Cholecystitis
Peptic ulcer disease
Pancreatitis
Disorders of intestinal motility

MISCELLANEOUS CAUSES OF CHEST PAIN

Thoracic outlet obstruction
Mediastinal emphysema
Iatrogenic

Pleurisy

Pleurisy results from inflammation of the parietal pleura. Inflammatory processes in the periphery of the lung that involve the overlying visceral pleura (e.g., pneumonia) frequently cause inflammation of the adjacent parietal pleura that, in turn, provokes pleuritic pain conveyed by somatic nerves. The parietal pleura that lines the interior of the rib cage and covers the outer portion of each hemidiaphragm is innervated by the neighboring intercostal nerves; when pain fibers in these regions are stimulated, pleuritic pain is localized to the cutaneous distributions of the involved neurons over the chest wall. In contrast, the parietal pleura that lines the central region of each hemidiaphragm is innervated by fibers that travel with the phrenic nerves; when this portion of the diaphragm is stimulated (e.g., by

contiguous inflammation), the resulting pain is referred to the ipsilateral shoulder or neck. This pain referral likely arises because visceral afferent input carried by the phrenic nerve converges with somatic input carried by the supraclavicular nerves that innervate the skin of the shoulder onto C3-5 spinal dorsal horn neurons (i.e., viscerosomatic convergence, a common feature of visceral pain leading to referred sensations). Thus, when this portion of the diaphragm is stimulated (e.g., by contiguous inflammation), the resulting pain is referred to the ipsilateral shoulder or neck.

Because of the somatic innervation of the parietal pleura, as well as the localization of most diseases of the lungs or chest wall to one hemithorax or the other, pleuritic pain tends to be limited to the affected region rather than be diffuse, with the exception of referral to the ipsilateral neck or shoulder. Pain may be variously described as “sharp,” “dull,” “achy,” “burning,” or simply a “catch.” There is a distinctive and unmistakable relationship to breathing movements, and taking a deep breath typically aggravates pleuritic pain.³¹ Coughing and sneezing can cause intense distress. Movements of the trunk, such as bending, stooping, or turning in bed, worsen pleuritic pain, so much so that patients often prefer the body position in which motion of the affected region is least.

An immediate onset of pleuritic pain suggests traumatic injuries or spontaneous pneumothorax. A sudden onset, often associated with dyspnea and tachypnea, also characterizes the clinical presentation of pulmonary embolism.³² A slower but still acute onset over minutes to a few hours often heralds the development of community-acquired bacterial (typically pneumococcal) pneumonia, especially when accompanied by fever and chills. Recurrent acute pleuritic pain is a feature of familial Mediterranean fever.³³ Finally, a gradual onset over days or weeks, often associated with features of chronic illness, such as low-grade fever, weakness, and weight loss, suggests tuberculosis or malignancy.

Pulmonary Hypertension

Persons with pulmonary hypertension may experience crushing or constricting substernal pain that at times radiates to the neck or arms, thus resembling the pain of myocardial ischemia.³⁴ Pain from pulmonary hypertension has been reported in patients with conditions that are acute (e.g., multiple or massive pulmonary emboli) and chronic (e.g., Eisenmenger syndrome, pulmonary vasculitis, or mitral stenosis). In addition, approximately half of the patients with primary pulmonary hypertension may have precordial chest pain.³⁵

In acute pulmonary hypertension resulting from massive pulmonary embolism, the pain may be caused by sudden distention of the main pulmonary artery and stimulation of mechanoreceptors.

In primary pulmonary hypertension, chest pain may be related to either (1) right ventricular ischemia because coronary blood flow is unable to meet the metabolic needs of the overloaded right ventricular muscle mass as the latter strives to maintain sufficient systolic and diastolic pulmonary arterial pressures³⁶ or (2) compression of the left main coronary artery by the dilated pulmonary artery trunk.³⁷

Although precordial pain related to the sudden onset of pulmonary hypertension can develop in cases of acute

Figure 31-1 Sites of referred pain in the chest. Some conditions are shown that should be considered as sources of referred pain in certain locations of the chest. Potential sources are listed in order of severity. Referred pain is generally due to viscerosomatic convergence, in which spinal cord neurons receive input from both visceral and somatic sources so that visceral pain can be interpreted as coming from a somatic source. Not shown are psychological causes of pain, which may constitute one of the most common entities, although it should remain a diagnosis only after considering and excluding these sources of pain.

pulmonary embolism, embolism-associated pain is much more likely to be pleuritic in character, whether or not there is pulmonary infarction.³⁸

Pulmonary artery stenosis may also cause substernal pain, presumably by the same pressure-overload mechanism through which pulmonary hypertension with right ventricular hypertrophy provokes pain.³⁹

TRACHEOBRONCHITIS

Pain of tracheal origin is generally felt in the midline, anteriorly, from the larynx to the xiphoid. Conversely, pain from either main bronchus is felt in the ipsilateral anterior chest near the sternum or in the anterior neck near the midline.⁴⁰ Whatever its origin, pain related to tracheobronchitis is typically described as “raw” or “burning” but may be “dull”

or “achy,” and exaggerated by deep breathing. This type of discomfort usually denotes the presence of viral or bacterial tracheobronchitis or, less often, a malignancy but can also be experienced during exposure to noxious gases. Tracheobronchial pain is thought to be mediated by bronchial C fibers. Experimentally induced tracheal pain can be abolished by vagal blockade⁴¹ or by vagotomy.⁴²

INFLAMMATION OR TRAUMA OF THE CHEST WALL (see Chapter 98)

Inflammation of, or trauma to, the joints, muscles, cartilages, bones, and fasciae that constitute the thoracic cage can cause chest pain.⁴³⁻⁴⁵ Fibromyalgia, fibrositis, and other rheumatologic disorders of the thoracic cage, such as ankylosing spondylitis, are known to cause pain and discomfort

in the chest.⁴⁶ Acute or chronic inflammation of the xiphoid process (xiphodynia)⁴⁷ and superficial thrombophlebitis of the chest wall (Mondor syndrome)⁴⁸ may also be uncommon sources of chest pain. Occasionally pain related to respiration may be experienced along the costal margins after vigorous exercise.⁴⁹ In addition, metastatic malignancy may present as painful lesions of the chest wall, sometimes with spontaneous rib fractures. Another confusing source of chest pain is infectious arthritis of the sternoclavicular joint or costochondral junctions, which is an increasing problem among injection drug users.⁵⁰

With *costochondritis*, chest wall pain arises from the costochondral cartilaginous junctions. It is usually described as “dull with a gnawing, aching quality.” There is little, if any, relationship to respiratory or other body movements. Tenderness to palpation is clearly localized to one or more of the costal cartilages.⁵¹ There may be redness, swelling, and enlargement of the costal cartilages (Tietze syndrome). The most common sites of costosternal perichondritis are the second, third, and fourth cartilages, but any part of the large cartilaginous shield along the central and lower portions of the anterior thoracic cage may be involved.

The pain of *intercostal neuritis* or *radiculitis*, which often originates from disorders of the cervicodorsal spine or nerve roots, is usually perceived in the rib cage. The superficial, spontaneous lancinating or electric shock–like pain of intercostal neuritis is typically felt over the cutaneous distribution of the involved nerves and may be worsened by taking deep breaths, coughing, and sneezing. Unlike pleurisy, neuritic pain is usually not aggravated by ordinary breathing; the diagnosis is supported by the presence of hyperalgesia or anesthesia on examination of the skin. In some patients with neuritis/radiculitis, the diagnosis becomes evident 2 or 3 days later with the development of the characteristic vesicular rash of herpes zoster over the involved dermatome. Painful radiculitis is also recognized as an important early manifestation of Lyme disease.⁵²

Injuries to the ribs (fracture) and thoracic cage muscles (strain, tears, or hematoma) are common causes of localized chest pain. The relationship of the pain to trauma is obvious in most instances, but diagnosis may be elusive, particularly if the inciting event is relatively minor (e.g., unnoticed episode of coughing) or when the onset of pain is delayed.

CARDIOVASCULAR DISORDERS

Mechanosensitive and chemosensitive afferent fibers are present in the myocardium.^{27,53} Chemical stimuli are believed to be the most important causes of cardiac pain, but mechanical distention or distortion may also play a role.⁵⁴ Sensory fibers travel from the heart to the spinal cord through the several cardiac nerves, the upper five thoracic sympathetic ganglia, and finally, the upper five thoracic dorsal roots; afferent fibers also reach the brain through the vagus nerves.⁵⁵ Cardiac pain is likely associated with activity in afferent fibers contained in the spinal afferent innervation of the heart.

Acute Coronary Syndrome

Acute coronary syndrome includes all conditions with myocardial ischemia caused by obstruction to coronary blood

flow. *Angina pectoris* due to myocardial ischemia is typically described as severe “pressure,” “squeezing,” or “constriction” with maximal intensity retrosternally or over the left parasternal border. Radiation to the neck, jaw, shoulder, or down the inner aspect of one or both arms may be present. It is usually induced by exercise but may be provoked by heavy meals, excitement, or extreme emotion. Pain tends to recur with repeated provocation, although its severity may vary. Pain usually subsides within 2 to 10 minutes with rest, and relief is accelerated by treatment with sublingual nitroglycerin.⁵⁶ A majority of patients with stable angina pectoris have significant reduction of at least one major coronary artery.⁵⁷ Prinzmetal or variant angina is similar in quality and location to typical angina pectoris but appears at rest rather than during exercise or increased myocardial oxygen needs.⁵⁸ In this syndrome the imbalance between myocardial oxygen supply and demand is postulated to arise from epicardial coronary artery vasospasm, usually superimposed on noncritical atheromatous vessel narrowing. Pain does not always accompany myocardial ischemia, and many electrocardiographically detectable episodes of ischemia in patients with stable angina pectoris are asymptomatic (“silent” ischemia).⁵⁹ Conversely, many individuals with angina-like chest pain have normal or nearly normal coronary arteries when studied by arteriography. As many as 30% of these noncoronary cases are classified as “syndrome X,”⁶⁰ with the development of chest pain attributed to either coronary microvascular spasm or heightened pain perception.^{60,61}

The pain of *acute myocardial infarction* is similar in location to that of angina pectoris but is typically much more severe in intensity, is not relieved by rest or nitroglycerin, often requires large doses of opiates for control, and is frequently associated with profuse sweating, nausea, dyspnea, and profound weakness.⁵⁶ During episodes of myocardial ischemia, the involved myocardium stiffens; when severe, this decrease in compliance may increase left ventricular end-diastolic filling pressure sufficiently to raise left atrial and pulmonary vascular pressures and cause pulmonary edema. Massive myocardial infarction may also lead to intractable hypotension and shock. Acute myocardial infarction may also be silent,⁶² especially in patients with diabetes mellitus.⁶³

Valvular Heart Disease

Chest pain can also arise from other *non-coronary artery disorders*, including mitral valve prolapse, myocarditis,⁵⁶ pericarditis, and hypertrophic cardiomyopathy.⁶⁴ It can also be related to cocaine use.

Patients with aortic stenosis may complain of angina-like pain on exertion. The frequency of chest pain is higher with aortic stenosis than with any other valvular heart disease and is found in two thirds of patients with severe disease.⁵⁶ Whenever a patient presents with progressive angina, dyspnea, or syncope, aortic stenosis should be considered. In contrast, patients with mitral stenosis or pulmonic stenosis infrequently experience chest pain.

Pericarditis

The pain of *pericarditis* is most commonly pleuritic and arises from spread of the inflammatory process across the pericardium to the adjacent parietal pleura. Typically pain

is worse in the recumbent position and while lying on the left side and is partially or completely relieved by sitting up, leaning forward, or lying on the right side. Occasionally, pericardial pain may be confused with anginal pain, but radiation to the arms is uncommon. Although there are few nociceptors in the pericardium, there appear to be nociceptors in the diaphragmatic portion of its parietal layer, which is innervated by sensory axons that travel in the phrenic nerves.⁶⁵ Stimulation of these fibers causes pain that may be sharp and steady and referred to the margins (ridge) of the trapezius muscles. Pain in this location is claimed to be specific for pericarditis because other diseases seldom cause discomfort in that area⁵⁶ (see Figure 31-1).

Pericardial friction rubs, presumably indicating underlying pericarditis, are more common than pericardial pain during the first few days after acute myocardial infarction and with worsening uremia.^{56,66} Other causes of pericarditis, usually associated with pericardial pain, are infections, often viral but also bacterial,⁶⁷ and connective tissue diseases (e.g., lupus erythematosus). Pericarditis, usually with fever, also can develop after open heart surgery (post-pericardiotomy syndrome) and after myocardial infarction (Dressler syndrome), both of which are considered to be autoimmune disorders.⁶⁸ Often, no diagnosis can be made, and pericarditis is considered idiopathic.

Cocaine Toxicity

Cocaine toxicity is associated with more visits to the emergency department for adverse reactions than any other illicit drug, and chief among the presenting complaints is chest pain.⁶⁹ Cocaine-associated chest pains typically begin approximately 60 minutes after injection or inhalation of the substance and last for 120 minutes.⁷⁰ The pain is most frequently substernal in location and pressure-like in character; it may be accompanied by shortness of breath and diaphoresis. Interestingly, clinical presentation may not differ among persons who develop myocardial infarction documented by biochemical markers and those who do not.

Cocaine-induced chest pain is undoubtedly provoked by the combined effects of an increase in myocardial oxygen demand owing to an increase in heart rate and in systolic and mean arterial pressures and a decrease in myocardial oxygen supply due to vasoconstriction of the epicardial coronary arteries.⁷¹

Despite the widespread use of cocaine and the frequent causal association (even among casual users) with chest pain, patients with chest pain who are seeking medical assistance are seldom queried about recent use of cocaine. Consequently, in the setting of cardiac symptoms, identification of cocaine exposure is a legitimate goal of cardiovascular history taking. In addition, this is an important question to ask because there is consensus that β -adrenergic blocking agents, which are indicated in acute coronary artery syndromes, may aggravate cocaine-induced myocardial ischemia by leaving the α -adrenergic system unopposed and potentially aggravating hypertension and coronary vasoconstriction. Thus, for cocaine-induced chest pain, nitroglycerin and calcium-channel blocking drugs (e.g., verapamil) constitute the treatments of choice. Cessation of cocaine use is essential for secondary prevention.

Disorders of the Aorta

Dissection of the aorta is usually associated with pain that is nearly always sudden and extremely severe at onset. Pain may be described, aptly, as “tearing” or “ripping” and often spreads widely, to the neck, throat, jaw, back, or abdomen, as the dissection extends from its point of origin.⁷² Frequent associated features are drenching sweats, nausea and vomiting, and light-headedness. Angina-like chest pain can also arise secondary to reduced coronary artery blood flow as a result of syphilitic aortitis or Takayasu vasculitis.

NONCARDIAC CHEST PAIN

The term *noncardiac chest pain* is used to describe an entity resembling angina. Noncardiac chest pain in the United States has an estimated annual incidence as high as 450,000 cases and causes considerable long-term morbidity as well as health care utilization. There are three main categories of extracardiac disease that cause angina-like chest pain: (1) musculoskeletal disorders of the chest wall, which may account for 10% to 20% of cases; (2) a variety of esophageal disorders, particularly gastroesophageal reflux, which may cause 30% to 40%; and (3) psychological factors, which may explain up to 50% of the total.

MUSCULOSKELETAL DISORDERS

Of the musculoskeletal causes of chest pain, the ones most commonly confused with angina are cervical neck disease, costochondritis, subacromial bursitis, intercostal muscle cramps, or congenital malformations such as pectus excavatum or carinatum. The best way to distinguish musculoskeletal pain from true angina is by reproduction of the pain with palpation or manipulation of the affected area. A history of recent trauma, chest infection, or cough can also support this diagnosis.

GASTROINTESTINAL DISORDERS

Receptors are present in the esophagus and may cause pain when activated by mechanical (spasm), chemical (acid reflux), or thermal (hot liquids) stimuli. Afferent nerves travel in both vagal and spinal (T3-T12) pathways.⁷³ Pain originating from the esophagus is usually referred to midline structures, such as the throat, neck, and sternal regions but may involve the arms as well. Stimulation of the distal end of the esophagus can cause pain directly over the heart.

Chest pain may arise either from esophageal reflux (the most common identifiable esophageal cause of chest pain) or from disorders of esophageal motility, such as diffuse esophageal spasm, achalasia, hyperactive lower esophageal sphincter, or nutcracker esophagus (a dysmotility disorder with high peristaltic pressures).^{74,75} Esophageal pain may mimic angina pectoris by its radiation to the neck and arms as well as relief by nitroglycerin.⁵⁶ Chest discomfort that lasts an hour or more, that leaves a residual dull achy discomfort, or that is associated with heartburn, odynophagia, or dysphagia should suggest pain of esophageal origin. Clinical history alone, however, cannot reliably distinguish pain originating from the esophagus from cardiac pain.

Lastly, other gastrointestinal disorders, such as cholecystitis, peptic ulcer disease, and acute pancreatitis, may present with pain that is perceived in the lower thorax.⁶⁵

PSYCHOLOGICAL FACTORS

Many patients experience chest pain for which no cause is ever found even after careful and thorough evaluation. Psychological factors clearly affect each person's interpretation of bodily sensations, and a psychiatric cause should be excluded in undiagnosed cases of chest pain.

An association between noncardiac chest pain and anxiety disorders, particularly panic disorder, has been reported. This is particularly well described in patients with mitral valve prolapse.⁷⁶ Patients with demonstrable heart disease may also have panic attacks. Alternatively, persons with chest pain may have psychological distress that is related to the panic syndrome and not the cardiac condition.

MISCELLANEOUS CAUSES OF CHEST PAIN

Obstructive lesions at the thoracic outlet may compress the brachial plexus and subclavian artery and can cause pain in the anterior chest and arms. *Thoracic outlet syndrome* is usually caused by compression of the neurovascular bundle by a cervical rib or a structural abnormality of the 1st rib or clavicle. Associated neuronal abnormalities have been described,⁷⁷ and electrophysiologic studies are useful not only to assist with the diagnosis but also to define which patients will respond to surgical decompression.⁷⁸ Chest pain may also arise from *iatrogenic causes*, such as pneumothorax following bronchoscopy or central venous catheter malposition.⁷⁹

EVALUATION AND TREATMENT OF CHEST PAIN

Given the wide variety of causes and seriousness of chest pain, considerable clinical judgment is required to decide which patients should be thoroughly evaluated and which tests should be used in the workup. In many instances, empirical therapy may need to be initiated even as evaluation proceeds, with subsequent readjustments in treatment protocols as more information is obtained that clarifies the clinical picture.

The evaluation of chest pain begins with a complete medical interview. The history may reveal nuances in the quality, location, duration, provoking events, and relieving measures, which serve to focus the subsequent evaluation. However, with few exceptions, such as evident injury to the chest wall, a specific diagnosis cannot be made with complete confidence from the clinical history alone. Physical examination may reveal evidence of pleural, lung parenchymal, or airway disease; localized chest wall involvement; or signs of mitral valve prolapse, aortic valve stenosis, or other cardiac abnormalities.

For adults who present to the emergency department with new-onset chest pain, the immediate concern is to identify and characterize potentially life-threatening

conditions, such as myocardial infarction, acute pulmonary embolism, or tension pneumothorax, requiring urgent management. Some diagnostic features are listed in [Table 31-2](#).

A standard 12-lead *electrocardiogram* (ECG), appropriate chest imaging, measurement of oxygen saturation and arterial blood gas levels, and blood chemistry profiles (e.g., troponin, D-dimer) often provide important data. In the appropriate clinical setting, some patients may require echocardiography or pulmonary function testing. Many other noninvasive or invasive tests are available for the evaluation of pain believed to be of respiratory, cardiac, or gastrointestinal origin. If the diagnosis remains uncertain, admission to chest pain observation units that offer a safe and effective means of care for patients with possible unstable angina who are considered to be at intermediate risk for cardiovascular events may be considered.

The most definitive treatment of chest pain, whatever its origin, is to find its cause and to cure it. The general principles of therapy for respiratory, cardiac, musculoskeletal, esophageal, and panic disorders are available, and the clinician is encouraged to refer to them. Chronic noncardiac chest pain is more difficult to manage, especially when its trigger cannot be found. Because of the complexities and difficulties in dealing with those few patients who have chronic, severe, and often refractory pain, referral to special pain centers staffed by a multidisciplinary team of specialists is recommended. At times, psychiatric consultation for specific treatment may be helpful.

CARDIAC ISCHEMIA

Initial evaluation of patients with suspected acute coronary syndrome including unstable angina or non-ST elevation myocardial infarction should always include a 12-lead ECG. Serial ECGs may be considered if the initial ECG is not diagnostic or if the patient is thought to have evolving myocardial ischemia or injury. Biomarker assessment for myocardial injury should include creatine kinase-MB, myoglobin, and cardiac-specific troponin. Patients who are chest pain-free and have no ischemic ECG changes or cardiac biomarker elevation should be considered for risk stratification with a cardiac functional study including exercise stress electrocardiography, stress echocardiography, or myocardial single-photon emission computed tomography imaging.⁸⁰⁻⁸² The indication for stress echocardiography has recently been clarified and includes the evaluation of acute chest pain and other chest pain syndromes, such as anginal equivalent, with or without heart failure, as well as risk assessment in symptomatic patients following revascularization procedures.^{81,82}

Acute ECG changes, such as ST segment deviations or deep T wave inversions, positive cardiac biomarkers or stress test results, or hemodynamic instability should prompt admission to an intensive care unit. Hospital admission may also be considered if the diagnosis remains uncertain despite initial limited evaluations. Available risk stratification models, such as the Thrombolysis in Myocardial Infarction score, may aid diagnosis and management.⁸³ Aspirin, preferably non-enteric-coated formulations, should be provided unless contraindicated or already taken by the patient. Other medications that may be useful in the management

Table 31-2 Differential Diagnosis of Chest Pain

Diagnosis	Pain	Characteristics	ECG	CXR	Associated Features
Angina pectoris	Substernal, constricting	Transient, effort-related	Local ST depression; occasional elevation	Normal	Relief with NTG
MI	Substernal, crushing	Persistent, severe	Local ST elevation or depression	Possible vascular congestion or cardiomegaly	Relief with opiates; possible hypotension; ↑ troponin
Pulmonary embolism	Pleuritic	Sudden onset with dyspnea	Nonspecific; occasional RV strain	Normal or opacities ± small pleural effusion	Risk factor/s for venous thrombosis
Pulmonary artery hypertension	Gradual onset	Associated with dyspnea, fatigue, and edema	Tall right precordial R waves, right axis deviation, RV strain	Prominent pulmonary arteries	Exclude pulmonary thromboembolism and interstitial lung disease
Bacterial pneumonia	Pleuritic	Onset in minutes to hours	Normal	Consolidation	Fever, productive cough
Pneumothorax	Sharp, unilateral	Sudden onset with dyspnea	Normal	Collapsed lung	Asthenic habitus, recurrence
Pericarditis	Pleuritic	Either side; gradual onset; pain referred to trapezius	Generalized ST elevation	Possible enlarged silhouette	Friction rub
Aortic dissection	Substernal, severe	Radiation to the back	Nonspecific; LVH or inferior MI	Widened mediastinum	Prostration, loss of pulse, aortic insufficiency
Esophageal spasm/reflux	Substernal	May mimic angina; burning	Normal or ST-T changes	Normal	Relief with NTG or antacids
Costochondritis	Dull-achy, localized	↑ by cough or deep breath	Normal	Normal	Localized tenderness
Herpes zoster	Sharp, unilateral	Dysesthesia	Normal	Normal	Vesicular rash

LVH, left ventricular hypertrophy; MI, myocardial infarction; NTG, nitroglycerin; RV, right ventricular.

of ischemic heart disease include nitroglycerin (sublingual or intravenous), β -blockers, angiotensin-converting enzyme inhibitors, nondihydropyridine calcium channel blockers, morphine sulfate (for persistent chest discomfort), antiplatelet agents (clopidogrel, prasugrel, ticagrelor, or glycoprotein IIb/IIIa inhibitor), and anticoagulant therapy (e.g., unfractionated heparin, enoxaparin, or fondaparinux).⁸⁴ Patients should be placed on strict bed rest, and supplemental oxygen should be provided, particularly if the patient is in respiratory distress or if oxygen saturation is less than 90%. Every patient with acute coronary syndrome should be evaluated for possible revascularization, preferentially percutaneous coronary intervention.⁸⁵ Management of non-ST segment elevation acute coronary syndromes by early invasive therapy improves long-term survival and reduces adverse cardiovascular events (late myocardial infarction and rehospitalization for unstable angina) compared with a more conservative approach.⁸⁶ Reperfusion therapy with fibrinolytic agents should be reserved for ST elevation myocardial infarction patients presenting to centers without angioplasty capability when anticipated delay to performing angioplasty is greater than 120 minutes from first medical contact. Urgent coronary artery bypass grafting surgery should be considered in acute coronary syndromes or ST elevation myocardial infarctions when primary angioplasty has failed or coronary anatomy is not amenable to percutaneous coronary intervention and high-risk features are present—including ongoing symptomatic ischemia, cardiogenic shock, heart failure, ischemic mitral regurgitation, ventricular septal defect, ventricular free wall perforation, or life-threatening arrhythmias.⁸⁷

Evaluation and management of variant or Prinzmetal angina consists of coronary angiography in patients with chest pain accompanied by transient ST segment elevation. Nitrates and calcium channel blockers may be given if no obstructive coronary artery lesions are evident on coronary angiography, with percutaneous coronary intervention reserved for those with significant coronary artery stenosis. Provocative testing may be considered in cases of diagnostic uncertainty if no contraindications exist.

For cardiac ischemic chest pain related to the use of cocaine or methamphetamine, nitroglycerin and calcium channel blockers may be considered as is immediate coronary angiography (preferred) or fibrinolytic therapy (if coronary angiography is not possible) if electrocardiographic ST elevation (or new ST segment depression or T wave changes) persists despite pharmacologic intervention. A combined α - and β -blocking agent, such as labetalol, may be helpful in patients with sinus tachycardia related to cocaine use if a vasodilator (nitroglycerin or calcium channel blocker) has been administered within the previous hour.

Patients with cardiovascular syndrome X may also benefit from medical intervention with nitrates, calcium channel blockers, and/or β -adrenergic blockers. Intracoronary ultrasonography, coronary angiography, 24-hour ambulatory ECG, provocative testing, or coronary flow reserve measurement may be considered to aid with diagnosis.

Risk stratification with exercise ECG (using the Bruce protocol or Duke treadmill score), exercise perfusion imaging, or exercise echocardiography should be considered for patients with symptomatic chronic stable angina who are able to exercise and have no contraindications to such testing. For those who are unable to exercise,

pharmacologic stress testing with dipyridamole, adenosine, dobutamine, or regadenoson nuclear myocardial perfusion imaging or dobutamine echocardiography is recommended unless contraindications to such testing exist.⁸⁸

PULMONARY EMBOLISM (see Chapter 57)

Pulmonary embolism is a life-threatening feature of venous thromboembolism and most frequently originates from deep venous thrombosis in the lower extremities.

Patients with acute pulmonary embolism who have elevated levels of troponin are at high risk for short-term mortality and adverse outcome events.⁸⁹ A recent meta-analysis of the different diagnostic strategies for suspected pulmonary embolism disclosed the positive likelihood ratios for high-probability ventilation-perfusion lung scan (18.3), computed tomography pulmonary angiography (CTPA) (24.1), and lower extremity venous ultrasonography (16.2).⁹⁰ The corresponding negative likelihood ratios were 0.05 for a normal or near-normal lung scan, 0.04 for a negative result on CTPA along with a negative result on ultrasonography, and 0.08 for a D-dimer concentration less than 500 µg/L by quantitative enzyme-linked immunosorbent assay. Using these tests, patients with a moderate or high pretest probability had a posttest probability of greater than 85%, while patients with a low or moderate pretest probability had a 5% posttest probability. Because of higher negative likelihood ratios, CTPA alone, a low-probability ventilation-perfusion lung scan, magnetic resonance angiography, a quantitative latex D-dimer test, and hemagglutination D-dimers can only exclude pulmonary embolism in those with a low pretest probability.⁹⁰

Patients with pulmonary embolism can be treated with either unfractionated heparin or low-molecular-weight heparin. Dabigatran, a direct thrombin inhibitor, was recently shown to be noninferior to warfarin for the treatment of venous thromboembolism and may be adopted as an acceptable treatment of pulmonary embolism in the future.⁹¹ Anticoagulation is maintained either for 3 to 6 months for events related to a transient risk factor or for greater than 12 months for recurrent venous thromboembolism.⁹²

PERICARDIAL DISEASE

Acute pericarditis is often associated with a pericardial effusion, diffuse concave ST segment elevation, and/or PR segment depression. Therapy for acute pericarditis involves identification and management of any underlying cause of the condition (e.g., infection or malignancy). In constrictive pericarditis, echocardiography can demonstrate the presence of pericardial thickening and calcification that limits diastolic filling of the ventricles and causes a characteristic biphasic pattern of venous return with a diastolic component that is equal to or greater than the systolic component. In selected patients, pericardectomy is a highly effective treatment of constrictive pericarditis.⁹³

CARDIAC TAMPONADE

Cardiac (or pericardial) tamponade is the presence of fluid within the pericardial sac leading to cardiac compression.

This, in turn, impairs ventricular diastolic filling and gives rise to the sensation of chest pain, dyspnea, tachycardia, falling systemic blood pressure, elevated venous pressure (characteristic loss of the atrial Y descent with maintenance of both the systolic atrial filling wave and the X descent), and pulsus paradoxus (an exaggerated inspiratory decrease in arterial systolic pressure > 10 mm Hg). Cardiac tamponade should be suspected whenever a patient presents with unexplained hypotension and/or pulsus paradoxus following myocardial infarction, chest trauma, percutaneous coronary intervention, or cardiac surgery. Other risk factors include anticoagulation therapy, malignancy, or an underlying connective tissue disease. A pericardial rub may be appreciated during physical examination. ECG changes compatible with acute pericarditis may be present as is an enlarged cardiac silhouette on chest films. Diagnosis is generally determined by two-dimensional echocardiography that demonstrates an inspiratory increase of right ventricular dimensions and decrease of left ventricular dimensions, compression of the right atrium, right ventricular diastolic collapse, and a heart that swings with cardiac contractions. Left atrial collapse is less common than right atrial collapse but is very specific for cardiac tamponade. There is commonly also an abnormal inspiratory increase of blood flow velocity through the tricuspid valve accompanied by a decrease in mitral valve flow velocity as well as dilation of the inferior vena cava with lack of inspiratory collapse. Aggressive volume loading and percutaneous or surgical pericardial fluid drainage leads to immediate relief of chest discomfort, dyspnea, venous hypertension, and pulsus paradoxus.^{93,94}

PULMONARY ARTERIAL HYPERTENSION

(see Chapter 58)

Initial evaluation of suspected pulmonary arterial hypertension generally consists of ECG, determination of arterial blood gas levels, a chest radiograph, pulmonary function testing, exercise capacity (6-minute walk test), brain natriuretic peptide or N-terminal brain natriuretic peptide, and noninvasive Doppler echocardiography with and without saline contrast.⁹⁵ Chronic thromboembolic disease is evaluated with ventilation-perfusion scanning and chest CTPA. Ultimately, right heart catheterization is required both to confirm the diagnosis and to assess the severity of the pulmonary hypertension. Testing for connective tissue disease or human immunodeficiency virus infection may be considered in patients with suggestive clinical histories for these disorders.⁹⁶ Acute vasoreactivity testing using inhaled nitric oxide (or other pulmonary vasodilators, including epoprostenol, adenosine, or sodium nitroprusside) should be performed for patients with pulmonary arterial hypertension to guide therapy.^{96a} Polysomnography is indicated for patients with a clinical history suggestive of obstructive sleep apnea. Treatment of pulmonary arterial hypertension includes potent vasodilators such as intravenous prostacyclin and the prostacyclin analogue treprostinil, inhaled iloprost or treprostinil, endothelin receptor antagonists (bosentan and ambrisentan), and cyclic guanosine monophosphate-specific phosphodiesterase type 5 inhibitors (sildenafil and tadalafil).^{96b} Calcium channel blocker therapy is reserved for those patients who demonstrate vasoreactivity at the time

of right heart catheterization. Pulmonary thromboendarterectomy may benefit patients with chronic thromboembolic pulmonary hypertension. Lung (preferably bilateral) transplantation or heart-lung transplantation may be considered for selected patients with New York Heart Association functional class III and IV symptoms.⁹⁷

THORACIC AORTIC DISSECTION

Rapid diagnosis and management are critical for patients with thoracic aortic dissection. Invasive aortography for the diagnosis of thoracic aortic dissection has been replaced by less invasive imaging techniques, including transesophageal echocardiography, contrast-enhanced chest *computed tomography* (CT) scan, and magnetic resonance imaging. All of these modalities yield clinically reliable data for both confirming and ruling out this condition. In one review, pooled sensitivity (98% to 100%) and specificity (95% to 98%) from 16 studies involving 1139 patients were comparable for these three less invasive imaging tools.⁹⁸ Pooled positive likelihood ratio was higher for magnetic resonance imaging than for transesophageal echocardiography or CT. In this review if the patient had a high-risk pretest probability (i.e., 50%), the posttest probability of thoracic aortic dissection following a positive result for each of these imaging tests was 93% to 96%; if the patient had a low-risk pretest probability (i.e., 5%), the posttest probability following a negative result from each of the imaging tests dropped to 0.1% to 0.3%.⁹⁸

PNEUMOTHORAX (see Chapter 81)

Spontaneous pneumothorax can be either primary or secondary. Patients with small primary pneumothoraces may be observed closely for either progression or resolution if they are clinically stable. Chest catheter or tube insertion is indicated if the pneumothorax enlarges or if the patient's clinical situation deteriorates, as well as in patients with large primary or secondary pneumothoraces. Patients with small secondary spontaneous pneumothoraces who are clinically stable may be either observed or managed with a chest tube depending on clinical severity and course of the pneumothorax.^{99,100}

TENSION PNEUMOTHORAX

A tension pneumothorax is a life-threatening condition that requires urgent management. High intrathoracic pressures develop because of ingress of air into the pleural space via a one-way valve process, which, in turn, prevents egress of air; this gives rise to vena caval compression, reduction in venous return, and diminished cardiac output. Radiographically, a tension pneumothorax presents as a complete collapse of the ipsilateral lung, depression/flattening of the ipsilateral hemidiaphragm, and shift of the mediastinum to the contralateral hemithorax. Therapy consists of emergency percutaneous aspiration or chest tube insertion.¹⁰⁰

PANCOAST TUMORS

Pancoast (superior sulcus) tumors require a definitive tissue diagnosis before initiation of therapy, which may, in selected

patients, include resection and/or chemoradiotherapy. Magnetic resonance imaging, both mediastinal and extrathoracic, is frequently performed to rule out involvement of adjacent neurovascular structures (brachial plexus, vertebral column, or subclavian vessels) that will influence surgical approaches.¹⁰¹

CHEST TRAUMA (see Chapter 76)

Blunt and penetrating chest trauma can give rise to chest pain related to hemothorax (bleeding into the pleural space); pneumothorax; rib, sternal, or clavicular fractures; or injury to the chest wall musculature.

As little as 5 mL of hemothorax can be appreciated on a decubitus chest radiograph, but a size of approximately 200 mL is required for it to be readily identified on an upright chest radiograph, where it will appear as blunting or, with greater volume of bleeding, a concave upward sloping of the fluid, in the ipsilateral costophrenic angle. The presence of an air-fluid level indicates a hemothorax. Chest CT is more sensitive than chest radiographs in detecting a small hemothorax; in addition, it may occasionally offer clues to the origin of the bleeding.

Rib fractures may be associated with injuries to the brachial plexus and subclavian veins (upper rib fractures) or spleen and liver (lower rib fractures). A flail chest resulting from at least two fracture sites on at least three consecutive ribs can create regional chest wall instability and respiratory distress. The sternum fractures most commonly at the body or manubrium, generally following direct trauma to the anterior chest or from deceleration. Significant posterior displacement of the sternum may be associated with trauma to the underlying cardiovascular structures. Chest CT is more sensitive than plain chest radiographs for detecting rib and sternal fractures.¹⁰⁰

GASTROESOPHAGEAL REFLUX (see Chapter 93)

Dyspepsia secondary to gastroesophageal reflux can be managed with proton pump inhibitors, histamine₂ receptor antagonists, or prokinetic agents. An empirical trial with these medications may be considered if the clinical history strongly supports the diagnosis of gastroesophageal reflux and if the patient is not at high risk for a gastrointestinal malignancy. Risk factors, such as use of nonsteroidal anti-inflammatory agents, should be investigated. Endoscopy may be necessary in some patients with unexplained dyspepsia and persistent symptoms. Recommendations for eradication therapy for *Helicobacter pylori*-positive dyspepsia have been published.¹⁰²

PANCREATITIS

Common causes of acute pancreatitis include gallstone disease (approximately 50% of cases) and alcohol abuse (20% to 25%). Patients typically complain of abdominal pain and vomiting, but chest pain may develop as well. Elevation of lipase has a higher sensitivity and specificity for pancreatitis than elevation of amylase perhaps because, compared to amylase, lipase is produced only by the pancreas. In addition, the half-life of lipase is longer than that

of amylase. Thus measurement of lipase is preferred. Other helpful laboratory tests include liver chemistry determinations, triglyceride level, and calcium level. When diagnostic doubt exists, abdominal imaging by contrast-enhanced CT may be beneficial. In addition to supportive measures, therapeutic endoscopic retrograde cholangiopancreatography may be considered, particularly if the acute pancreatitis is severe, due to gallstones, or when cholangitis, jaundice, or a dilated common bile duct is present. The presence of cholangitis is an indication for endoscopic sphincterotomy or duct drainage by stenting. Image-guided fine-needle aspiration is recommended for patients with significant pancreatic necrosis, who may require débridement if infection is present.^{103,104}

Key Points

- Chest pain is characterized by an unpleasant sensation that is either localized to the thorax or believed to originate from structures located there. It may announce the presence of severe, occasionally life-threatening disease.
- Pain arising from *visceral* organs (e.g., heart or gastrointestinal tract) differs in many ways from that arising from *somatic* structures, such as the skin. Visceral pain is difficult to localize, is diffuse in character, and is typically referred to somatic structures. Visceral pain is also often associated with greater autonomic and motor responses than is somatic pain.
- Visceral and somatic innervations differ in relation to the density of innervations and spinal pattern of termination. In general, the number of visceral afferent fibers is less than the number of somatic afferent fibers, and the rostrocaudal spread of visceral afferent fiber terminals in the spinal cord is considerably greater than the spread of central terminals from somatic afferent fibers. The low number of visceral afferents and greater intraspinal spread is responsible for loss of spatial discrimination, consistent with the diffuse, difficult-to-localize nature of visceral pain.
- Pain is both hard to define and difficult to measure. Two widely used techniques, namely rating scales and questionnaires, are often used in clinical and epidemiologic studies of chest pain. Although rating scales constitute the simplest measurement of pain, the sensation of pain has many more components than just its intensity; thus, a single-dimensional rating scale leaves many aspects of the sensation undocumented.
- Because of the proximity of the various organs and the vagaries of perception of pain of visceral origin, pain arising from the various viscera in the thoracic cavity and from the chest wall is often qualitatively similar and exhibits overlapping patterns of referral, localization, and quality. This leads to difficulty in the differential diagnosis of chest pain.

INTRODUCTION

Viral infections are important causes of disease of the respiratory tract. The common cold is the most frequently encountered infectious syndrome of humans, while influenza continues to be a major cause of mortality and serious morbidity worldwide. Respiratory viral infections frequently complicate the course of patients with *chronic obstructive pulmonary disease* (COPD) and asthma. As the number of immunocompromised persons in the population has increased, infections due to cytomegalovirus and other herpes viruses, adenoviruses, and paramyxoviruses have assumed increasing importance in pulmonary medicine. Finally, recent years have seen the emergence of new viral respiratory pathogens, including hantaviruses, human metapneumovirus, avian influenza A viruses, and the *severe acute respiratory syndrome* (SARS) and *Middle East respiratory syndrome* (MERS) coronaviruses. This introductory section outlines general concepts of respiratory viral infections and their associated clinical syndromes. The following sections then provide a review of the major viral pathogens infecting the respiratory tract.

CLASSIFICATION

Viruses of importance in the respiratory tract ([Table 32-1](#)) include those considered to be principal respiratory viruses,

the replication of which is generally restricted to the respiratory tract, and others in which respiratory involvement is part of a generalized infection. Virus classification depends in part on the type and configuration of the nucleic acid in the viral genome, the characteristics of the viral structural proteins, and the presence or absence of an envelope surrounding the virus particle. The number of distinct antigenic types within each of the virus families also varies.

TRANSMISSION

The routes by which the different respiratory viruses spread from person to person are variable and include combinations of contact, droplet, and aerosol transmission. For example, rhinovirus and *respiratory syncytial virus* (RSV) are primarily spread by direct contact with contaminated skin and environmental surfaces followed by self-inoculation of virus onto the nasal mucosa or conjunctiva. Other viruses, such as measles and varicella-zoster viruses, spread as small-particle aerosols. Other viruses may spread by means of larger-particle aerosols over short distances (1 m). The relative importance of the various transmission routes under natural conditions for each virus varies and in many cases is unknown.

Table 32-1 Viral Infections of the Respiratory Tract

Group	Nucleic Acid	Envelope	Types	Disease/Syndrome*
Adenovirus	DNA	No	1–47	Common cold; bronchitis; bronchiolitis; pharyngoconjunctival fever; acute respiratory disease (ARD) in military recruits; pneumonia
Coronavirus	RNA	Yes	229E, OC43, SARS-CoV, MERS-CoV	Common cold, severe acute respiratory syndrome (SARS), Middle East respiratory syndrome (MERS)
Hantavirus	RNA	Yes	Multiple	Acute respiratory distress, pneumonitis
Orthomyxovirus Influenza virus	RNA	Yes	A, B, C	Influenza; common cold; pharyngitis; croup; bronchitis; bronchiolitis; pneumonia
Paramyxoviruses Measles virus Parainfluenza virus Respiratory syncytial virus Human metapneumovirus	RNA	Yes	1–4 A, B A, B	Measles; pneumonia; bronchiectasis Common cold; croup; bronchitis; bronchiolitis; pneumonia Common cold; croup; bronchitis; bronchiolitis; pneumonia Bronchiolitis, common cold
Picornaviruses Enterovirus Coxsackievirus	RNA	No	1–24	Type A21 colds and ARD; others (types 2, 4, 5, 6, 8, 10); herpangina
Echovirus Rhinovirus			1–34 1–100	Common cold (importance uncertain) Common cold
Herpes viruses Herpes simplex virus	DNA	Yes	1, 2	Acute pharyngitis in normal persons; chronic ulcerative pharyngitis; tracheitis; pneumonia in immunosuppressed patients
Cytomegalovirus			1	Mononucleosis; acute and chronic pharyngitis; pneumonia in immunosuppressed patients
Varicella-zoster virus			1	Pneumonia in normal persons and immunosuppressed patients
Epstein-Barr virus			1	Mononucleosis; acute and chronic pharyngitis
Human herpesvirus 6			1	Pneumonia in immunosuppressed patients
Filovirus	RNA	Yes	Marburg; Ebola 1, 2	Pharyngitis as an early manifestation of hemorrhagic fever
Human immunodeficiency virus	RNA	Yes	1, 2	Pharyngitis with primary infection; secondary pulmonary infections due to immunodeficiency
Papillomavirus	DNA	No	>60	Laryngeal and tracheobronchial papillomatosis

*Bacterial infections, including sinusitis, otitis media, and pneumonia, complicate respiratory virus infection. Also, infection with the respiratory viruses may precipitate attacks of asthma and cause exacerbations in patients with chronic obstructive pulmonary disease.

PATHOGENESIS OF INFECTION

The initial sites of infection and pathogenesis differ for the various virus groups. Some, such as rhinovirus, are associated mainly with upper respiratory tract involvement. Others, such as influenza, commonly invade the lower airways and sometimes pulmonary parenchyma in addition to causing upper airway disease. The viruses also differ in the relative contributions to the clinical manifestations of disease from damage due to direct viral mechanisms and damage due to host immune responses and inflammation.

An additional important feature of respiratory virus infections is their effect on the resident bacterial flora of the upper airways. Respiratory virus infections alter bacterial colonization patterns, increase bacterial adhesion to respiratory epithelium, and reduce mucociliary clearance and phagocytosis. These impairments of host defenses by viruses allow colonization by pathogenic bacteria and invasion of normally sterile areas, such as the paranasal sinuses, middle ear, and lower respiratory tract, resulting in secondary infection.

CLINICAL SYNDROMES

As shown in [Table 32-1](#), infection by one of the respiratory viruses may result in more than one clinical syndrome. Similarly, a particular syndrome can result from infection with different viruses. The poor correlation of agent and syndrome makes specific etiologic diagnosis on clinical grounds inaccurate, although knowledge of the seasonal patterns of infection may be helpful. Moreover, infection with a single virus may cause disease at multiple levels of the respiratory tract.

COMMON COLD

There is no universally accepted, standard definition of a cold, but the term is usually used to refer to acute rhinitis with variable degrees of pharyngitis. Systemic complaints are absent or modest in severity and fever is unusual. Allergic diseases of the upper airway often have clinical manifestations similar to those of colds. Colds are frequently associated with involvement of the middle ear, likely due to

Table 32-2 Viruses Associated with the Common Cold

Virus	Percentage of Cases*
Rhinovirus	40
Coronavirus	10
Parainfluenza virus	10–15
Respiratory syncytial virus	
Influenza virus	
Adenovirus	
Other viruses (enterovirus, rubeola, rubella, varicella)	5
Presumed undiscovered viruses	20–30
Group A β -hemolytic streptococci†	5–10

*Estimated percentage of colds annually.

†Included because differentiation of streptococcal and viral pharyngitis is not possible by clinical means.

eustachian tube dysfunction. Colds are associated with symptomatic otitis media in approximately 2% of cases in adults and in a higher proportion in young children. Colds are frequently associated with sinus mucosal thickening or secretions on computed tomography scans but rarely result in symptomatic sinusitis. Vertigo associated with viral labyrinthitis may also be seen.

The common cold syndrome is caused by any one of a large number of antigenically distinct viruses found in four principal groups (Table 32-2). Epidemiologic studies have indicated that on an annual basis, any one antigenic type of virus is responsible for less than 1% of all colds. Since the discovery of the respiratory viruses in the 1960s, rhinovirus has emerged as the prototype common cold virus (Fig. 32-1).

The recommended approach to colds is to use individual remedies to treat specific symptoms. Nasal sprays containing decongestants should be used for no more than 3 days, to avoid a rebound vasomotor rhinitis. Cough syrups containing expectorants are of unproven value in common colds. Symptoms of sneezing and rhinorrhea can be alleviated with nonselective antihistamines such as brompheniramine, chlorpheniramine, or clemastine fumarate,¹ but treatment with selective H₁ inhibitors is not effective. Studies of pseudoephedrine have demonstrated measurable improvements in nasal air flow consistent with a decongestant effect.² Nonsteroidal anti-inflammatory drugs such as naproxen moderate the systemic symptoms of rhinovirus infection. However, the use of the decongestant phenylpropanolamine has been shown to be associated with an increased risk of hemorrhagic stroke.³ Topical application of ipratropium, a quaternary anticholinergic agent that is minimally absorbed across biologic membranes, reduces rhinorrhea significantly in naturally occurring colds. This agent probably exerts its major effect on the parasympathetic regulation of mucous and seromucous glands. Importantly, most over-the-counter cough and cold remedies have not been studied in pediatric populations, where they may be associated with significant side effects.⁴

PHARYNGITIS

Pharyngitis most often presents as part of the common cold syndrome and thus is usually associated with the same

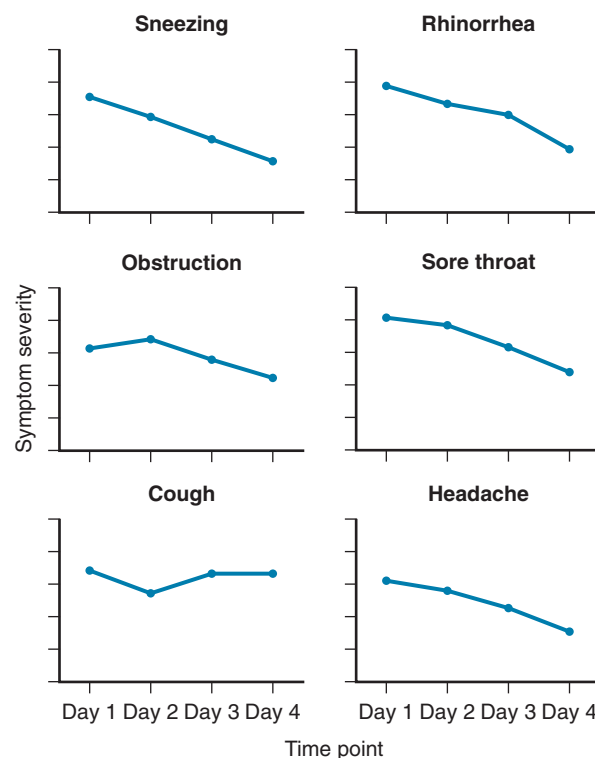

Figure 32-1 Some common clinical features of rhinovirus colds (105 natural infections). Graphs show symptom severity by time point. (Adapted from Gwaltney JM Jr, Hendley JO, Patrie JT: Symptom severity patterns in experimental common colds and their usefulness in timing onset of illness in natural colds. *Clin Infect Dis* 36:724–723, 2003, Fig. 2.)

Table 32-3 Important Microbial Agents Associated with Acute Pharyngitis

Pharyngitis with colds and influenzal illness (no exudate)	Rhinovirus Influenza virus Coronavirus Respiratory syncytial virus
Exudative pharyngitis (exudate is not present in all cases)	<i>Streptococcus pyogenes</i> (group A β -hemolytic streptococcus) Mixed anaerobic infection (Vincent angina and peritonsillar abscess) Adenovirus Herpes simplex virus Epstein-Barr virus <i>Corynebacterium diphtheriae</i> (pseudomembrane)

viruses that cause colds. In some cases, pharyngeal symptoms predominate to a degree that overshadows other complaints. The kinins are potent stimulators of pain nerve endings, and high levels of bradykinin and lysylbradykinin are present in nasal secretions of patients with rhinovirus-induced colds. Intranasal application of bradykinin promotes sore throat and nasal symptoms in volunteers, supporting a role for these agents in the pathogenesis of cold symptoms.⁵

The respiratory viruses causing pharyngitis can be divided into two groups: those associated with a pharyngeal or tonsillar exudate and those without such an exudate (Table 32-3). Pharyngitis is often a prominent complaint with adenovirus and influenza virus infection. Also, some

viruses are associated with other types of *enanthems*, meaning lesions on the mucous membranes, such as vesicles and ulcers. Coxsackie A viruses are associated with the condition herpangina, a painful, often febrile pharyngitis of children and young adults characterized by vesicular lesions of the soft palate.

Viruses in the herpes family cause a small proportion of cases of pharyngitis. Primary infection with herpes simplex virus manifests as an acute vesiculoulcerative pharyngitis or gingivostomatitis that may have an exudative character. In immunocompromised patients, herpes simplex virus causes large, shallow ulcers of the mucosa that are chronic and progressive if untreated. Epstein-Barr virus mononucleosis characteristically has an acute exudative pharyngitis. Mononucleosis due to cytomegalovirus infection may have a nonexudative pharyngitis that is acute or chronic, and rarely, cytomegalovirus causes oral ulcerations in immunosuppressed patients. Pharyngitis can arise during primary infection with *human immunodeficiency virus* (HIV). Viruses in the hemorrhagic fever group produce an acute pharyngitis early in the disease, before skin lesions appear. Exudative pharyngitis is a common clinical manifestation in Lassa fever.

Typically, sore throat accompanied by nasal symptoms is more likely to be viral in nature. Infection with mixed anaerobic bacteria (Vincent angina) or *Corynebacterium diphtheria* is also in the differential diagnosis of exudative pharyngitis. The treatment of most cases of viral pharyngitis is symptomatic.

ACUTE BRONCHITIS

The diagnosis of acute bronchitis is usually applied to cases of acute respiratory disease with severe and prolonged cough that continues after other signs and symptoms of the acute infection have subsided. Cough appears during the first week of illness in 30% of rhinovirus colds in young adults and in 80% or more of cases of influenza A virus infection, in which it is often prolonged. Adenovirus infections characteristically involve the tracheobronchial tree, with resultant bronchitis that, in military populations, is part of the syndrome of acute respiratory disease.

The mechanisms of cough production in viral infection are not well understood but may include direct damage to the respiratory mucosa, release of inflammatory substances in response to the infection, increased production and/or decreased clearance of respiratory secretions, and stimulation of airway irritant receptors. Intranasal application of several prostaglandins also produces cough in uninfected volunteers.⁵ Infection may also enhance airway reactivity, leading to increased sensitivity to cold air and pollutants such as smoke.

The differential diagnosis of acute bronchitis includes nonviral infections and noninfectious etiologies such as cough-variant asthma. *Bordetella pertussis*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae* infections cause prolonged cough. In otherwise healthy persons, workup of acute cough should be directed toward determining the presence of pneumonia and, if this is not present, then treatment with antibacterial agents is of no benefit.⁶ Symptomatic treatment is directed at the suppression of cough. In children, a single nocturnal dose of honey is as effective

as dextromethorphan in suppressing night time coughing,⁷ but honey should not be administered to infants younger than 1 (due to risk of infant botulism).

INFLUENZA-LIKE ILLNESS

The clinical syndrome of influenza is characterized by the rapid onset of constitutional symptoms, including fever, chills, prostration, muscle ache, and headache, concurrent with or followed by upper and lower respiratory tract symptoms. Systemic symptoms tend to dominate for the first several days of illness, whereas respiratory complaints, particularly cough, predominate later in the first week of illness. Photophobia, excess tearing, and pain with eye movement are common early in the illness. Mild conjunctivitis, clear nasal discharge without obstruction, pharyngeal injection, and small tender cervical lymph nodes are frequently present. Fever may peak at 39° C to 40° C or higher and can last for 1 to 5 days. Persistent nonproductive cough, easy fatigability, and asthenia are common in the second week of illness.

Influenza type A and B viruses are the most important causes of the influenza syndrome, particularly when the illness presents in an epidemic form. However, the syndrome can also be seen in association with infection by other viruses, including adenovirus, parainfluenza, and RSV. The characteristic clinical features of influenza and its epidemic nature usually permit the practitioner to make an accurate diagnosis during recognized epidemics of influenza virus infection, particularly if cough and fever are present.⁸ Specific antiviral therapy is effective if given early in the course of the illness (see the section on [influenza virus](#)). Symptomatic treatment (bed rest, oral hydration, antipyretics, and antitussives) is also beneficial. Fever should be treated in certain clinical situations, such as in children with previous febrile convulsions or patients with preexisting cardiac disease. Because of its possible association with Reye's syndrome, aspirin must be avoided in pediatric patients.

CROUP

The croup syndrome of children is characterized by an unusual brassy or barking cough (see [Audio 30-3](#)) that may be accompanied by inspiratory stridor, dyspnea, and hoarseness.^{8a} The symptoms are often preceded by several days of upper respiratory illness and are typically worse at night. Croup is seen primarily in children younger than 6. The term *acute infectious croup* or *laryngotracheobronchitis* is applied to a contagious disease that affects otherwise healthy children, often associated with a respiratory illness in the family. The term *acute spasmodic croup* is applied to a similar syndrome that is most common in young children prone to recurrent attacks precipitated by respiratory viral infections and possibly allergic or other factors. In these children, fever is frequently absent and symptoms often abate within several hours.

Most children with acute laryngotracheobronchitis have symptoms of decreasing intensity over several days and can be managed at home. However, increasing laryngeal obstruction can be associated with respiratory insufficiency. This is manifested by restlessness, air hunger, stridor

Figure 32-2 Laryngotracheobronchitis. Anteroposterior (A) and lateral (B) neck radiographs of a 2-year-old child with croupy cough, inspiratory stridor, and fever. The anteroposterior view shows subglottic narrowing, referred to as the “steeple” sign (arrow), characteristic of laryngotracheobronchitis. Lateral view shows ballooning of hypopharynx resulting from laryngeal obstruction. (Courtesy Joan McIlhenny, MD, Department of Radiology, University of Virginia Medical Center.)

at rest, use of accessory muscles, and intercostal retractions and may be followed by development of exhaustion with severe hypoventilation, cyanosis, and cardiovascular collapse. A fluctuating course is typical.

Radiologic examination of the upper airway shows glottic and subglottic edema (Fig. 32-2, eFig. 32-1) and helps to differentiate the disorder from acute bacterial epiglottitis. However, radiographs are limited in accuracy and, when the diagnosis is uncertain, radiologic and pharyngeal examination should be avoided because of the risk of cardiorespiratory arrest in acute epiglottitis. Emergency assessment by an otolaryngologist or an anesthesiologist is indicated in this situation.

The acute infectious croup syndrome has been associated principally with infection by one of the parainfluenza viruses, as well as RSV, influenza A and B viruses, adenoviruses, and rhinovirus. Measles is an important cause of severe croup in the developing world, and influenza A epidemics also are associated with severe croup. The differential diagnosis of croup includes acute bacterial epiglottitis, diphtheritic croup, asthma, and intrinsic or extrinsic upper airway obstruction related to an aspirated foreign body, allergic angioedema, and retropharyngeal abscess.

Because the majority of hospitalized children are hypoxicemic, oxygen is the mainstay of treatment for severe disease. Humidified air, or mist therapy, is commonly used, but the value of mist therapy has not been proven, and removal of the child from the parents and placement in a mist tent can be more distressing than beneficial to the child.

Administration of nebulized racemic epinephrine is commonly used for symptomatic relief in croup. It is believed that α -adrenergic stimulation by this drug causes mucosal vasoconstriction, leading to decreased subglottic edema. The onset of action is rapid, often within minutes, but the duration of relief is also limited, lasting 2 hours or less. Therefore, treated subjects should be observed closely for clinical deterioration. Although symptomatic relief is considerable, use of epinephrine is not associated with improve-

ments in oxygenation. Steroids have been shown to confer significant benefits in the management of mild, moderate, and severe croup, including more rapid improvement in symptoms, reduced length of hospital stay, and reduced rates of intubation. Administration of single-dose steroid therapy in this setting has not been associated with significant side effects and should probably be used in any patient ill enough to require an emergency department or clinic visit.⁹

Antiviral agents have not been tested for efficacy in this situation, although the potential benefit of antiviral therapy in the typical self-limited course of croup would likely be limited. Since croup is a viral illness, antibiotic therapy is of no benefit.

BRONCHIOLITIS

Bronchiolitis is an acute inflammatory disorder of the small airways characterized by obstruction with “air trapping,” hyperinflation of the lungs, and atelectasis typically seen in children younger than 2. After a several-day prodrome of mild upper respiratory tract symptoms, patients typically present with inspiratory and expiratory wheezing. The clinical features, which include tachypnea, intercostal and suprasternal retractions, nasal flaring, hyperresonant chest, wheezing, and inspiratory rales, usually lead to an accurate clinical diagnosis. The infant is often afebrile and, in mild cases, symptoms resolve within several days. Chest radiographs show increased lung volumes with flattening of the diaphragms, peribronchial thickening (eFig. 32-2), and often atelectasis or parenchymal consolidation indicative of concurrent bronchopneumonia (Fig. 32-3). Chest computed tomography (CT) may show bronchial wall thickening and areas of increased attenuation representing atelectasis mixed with areas of decreased attenuation due to small airway inflammation and obstruction producing air trapping (eFig. 32-3). The white blood cell count and differential count are usually within normal limits.

Figure 32-3 Respiratory syncytial virus pneumonia. Frontal chest radiograph in an intubated infant shows bilateral peribronchial interstitial thickening and right upper and left lower lobe consolidation; the right upper lobe opacity is associated with mild volume loss. (Courtesy Michael Gotway, MD.)

The majority of cases in which an etiologic agent has been identified are associated with RSV. Other viruses associated with bronchiolitis include human metapneumovirus, bocavirus, parainfluenza virus, influenza A and B viruses, adenovirus, measles, and rhinoviruses. The major differential diagnostic consideration is asthma, which is uncommon in children younger than one year old.

Correction of hypoxemia is the most important aspect of managing lower respiratory tract disease. Studies of corticosteroid therapies have found no consistent benefit. Studies of bronchodilators have reached conflicting results, and bronchodilating drugs may contribute to increased restlessness and cardiovascular stress, so guidelines do not suggest that bronchodilators be used routinely. One recent randomized trial suggests that “on-demand” use of inhaled racemic adrenaline may result in decreased length of stay in infants hospitalized with bronchiolitis.¹⁰ Because of the dehydrating effect of tachypnea and reduced oral intake in some hospitalized infants, parenteral rehydration is often necessary, but care must be taken to avoid inducing hyponatremia. Aerosol treatment with the synthetic nucleoside ribavirin has been associated with reductions in virus titers but inconsistent clinical benefits. Antibacterial drugs, including azithromycin, are of no benefit.¹¹

PNEUMONIA

Viruses are important causes of pneumonia in both adults and children. They have been associated with up to 40% of radiographically proven pneumonias in hospitalized adults and are estimated to cause 16% of total pneumonias in pediatric outpatients and up to 49% in hospitalized infants. These figures may underestimate the importance of viral infections as a cause of pneumonia, particularly in outpatients, because of the insensitivity of viral diagnostic methods and because of the lack of chest radiographs in

many patients with acute viral infections. Also, because viral infections may be complicated by secondary bacterial pneumonias, invasive procedures would be necessary to differentiate among pure viral pneumonias, secondary bacterial pneumonias, and mixed viral and bacterial infections.

Normal Host

The relative importance of the different viruses as causes of pneumonia depends on the season and the age distribution of the population under study. During outbreaks, influenza virus accounts for more than 50% of viral pneumonia in adults. In addition, RSV, adenovirus, parainfluenza virus, and varicella virus cause pneumonia in normal adults. Unusual viruses continue to emerge in epidemics of severe acute pneumonitis, including hantavirus, coronavirus (SARS), and avian influenza A viruses.

In children, RSV, parainfluenza virus, and adenovirus, in addition to influenza viruses, are the most important causes of pneumonia. Measles virus pneumonia affects children and adults during epidemics in susceptible populations. There are reports of cases of pneumonia in adults and children attributable to rhinovirus, but the evidence that these viruses are definite causes of pneumonia is circumstantial.

The clinical and radiographic features of sporadic cases of viral pneumonia are usually not sufficiently characteristic to permit specific viral diagnosis or differentiation from bacterial pneumonias on clinical grounds alone. Exceptions include measles (eFig. 32-4) and varicella pneumonia, in which the associated rash establishes the diagnosis. Therefore, attention is first directed at excluding primary or secondary bacterial pneumonia. Tests to detect viral antigens or nucleic acid are increasingly available and are rapidly being adopted as the preferred approaches for establishing the etiologic diagnosis^{11a,b} (see Chapter 17).

Treatment of viral pneumonia in the normal host is supportive in nature and directed at early antimicrobial therapy of secondary bacterial infections, if present. Specific antiviral therapy may be beneficial and is discussed with the individual pathogens. Viral pneumonias with extensive involvement of lung tissue may require prolonged ventilatory assistance and pulmonary rehabilitation. Some cases of viral pneumonia have a rapid and relentless fatal course, with generalized alveolar and interstitial opacities, development of the *adult respiratory distress syndrome* (ARDS), and progressive respiratory failure.

Immunocompromised Host

Viral pneumonia can be an important problem for the increasing number of persons in the population who have deficiencies in immunity as the result of cytotoxic chemotherapy, organ transplantation, and the *acquired immunodeficiency syndrome* (AIDS). The major respiratory viruses that affect normal persons may also cause pneumonia in impaired hosts; severe and prolonged pneumonias due to adenovirus, respiratory syncytial, influenza, measles, or parainfluenza virus can develop in such patients. Immunocompromised patients can also shed respiratory viruses for prolonged periods and thus be responsible for extensive transmission of infection to others. In addition, these individuals may develop pneumonia due to viruses, such as cytomegalovirus, that rarely cause lower respiratory tract

disease in normal hosts. Cytomegalovirus causes severe primary viral pneumonia (see eFigs. 91-3, 91-4, and 91-5), as well as predisposing patients to bacterial and fungal superinfections because of its immunosuppressive effects.^{11c,d} Varicella-zoster and herpes simplex virus pneumonias are relatively uncommon but serious infections in immunosuppressed patients.

MAJOR VIRAL PATHOGENS

ADENOVIRUS

Adenovirus is a medium-sized (65 to 80 nm), nonenveloped virus with a genome composed of linear double-stranded DNA¹² (Fig. 32-4). Currently, 47 antigenic types of adenovirus are associated with human infection, although not all types have been associated with human disease. The protein coat of the virus is composed of 252 hexagonal and pentagonal capsomeres in an icosahedral array with long projecting fibers at each vertex. These fibers are thought to be the site of host cell attachment. Adenoviruses type 2 and 5 and coxsackie B viruses use the same receptor, designated the *coxsackie virus and adenovirus receptor* (CAR), whose usual function is to mediate cell interactions with extracellular matrix proteins. Some adenoviruses use the complement regulatory protein CD46 as a cellular receptor. Virus entry into the cell is also promoted by interaction of the penton base of the virus with alpha-V integrins. Viral type-specific antigens, which give rise to neutralizing antibody, are present on the hexons and fibers of the capsid. The hexons also contain a complement-fixation antigen with cross-reactivity among the mammalian adenoviruses.

Epidemiology and Transmission

The adenoviruses that cause human disease do not have nonhuman reservoirs, although nonhuman adenoviruses are found in other species. Some serotypes, especially types

1 and 2, routinely infect infants and young children, who then have prolonged asymptomatic viral shedding from the respiratory and *gastrointestinal* (GI) tracts. Other types, including those that have been most often implicated in respiratory disease (e.g., types 3, 4, and 7), are acquired later in life, characteristically in epidemic settings. In most instances, viral transmission probably takes place by direct contact with infectious secretions. However, the explosive nature of adenoviral acute respiratory disease in military recruits probably reflects airborne spread.

Most community adenovirus respiratory disease has been recognized in the summer months in association with outbreaks or sporadic cases of febrile pharyngitis or bronchitis. Nosocomial outbreaks of adenovirus infection have arisen in hospital wards, special care units, and psychiatric facilities. New variants of adenovirus have occasionally emerged and have been associated with outbreaks worldwide. Since 1996, a specific variant of *adenovirus type 7* (Ad7d2) has been responsible for several civilian outbreaks and a large military outbreak.¹³ More recently, *adenovirus type 14* (Ad14), a previously rare serotype, has been responsible for outbreaks of disease both in the military and in civilian populations.¹⁴⁻¹⁶ Most cases have been relatively mild febrile respiratory illnesses, but some cases have been seen with severe pneumonia requiring hospitalization. Infection with adenovirus type 36 is associated with weight gain in mice,¹⁷ and serologic positivity for this serotype appears to be more common in adults and children with obesity.¹⁸

Pathogenesis

Adenoviruses have been isolated from the upper airway, eye, urine, stool, and rarely, blood. The incubation period for naturally acquired adenovirus disease of the respiratory tract is usually 4 to 7 days but may be up to 2 weeks.

Cytopathologic changes have also been observed in bronchial epithelial cells,¹⁹ and crystalline arrays of virus particles have been found in alveolar lining cells of infected persons with severe illness.²⁰ The extent of damage to the respiratory tract in nonfatal adenovirus respiratory disease is not well defined but may result from a combination of direct viral mechanisms and host-related inflammatory responses to infection. In cases of fatal adenovirus pneumonia, bronchial epithelial necrosis, bronchial obstruction, and interstitial pneumonia have been seen.²¹ Cells containing large basophilic, intranuclear inclusions, so-called “smudge cells,” appear to be characteristic (Fig. 32-5). In lung transplant recipients, necrotizing bronchocentric pneumonia with diffuse alveolar damage has been reported.²²

Clinical Illness

Adenovirus Respiratory Disease. The nonpneumonic respiratory syndromes associated with adenovirus infection include acute respiratory disease of military recruits and pharyngoconjunctival fever of civilians, which have similar characteristics (Fig. 32-6). Adenovirus respiratory disease typically involves the pharynx as a moderate to severe, sometimes purulent, pharyngitis. Also characteristic of this disease is marked tracheitis, bronchitis, or tracheobronchitis, as well as rhinitis and conjunctivitis. Conjunctivitis is not a feature of infection with the other major respiratory

Figure 32-4 Photoelectron micrograph showing human adenovirus type 2. Each virion contains a lobulated group of three adenosomes, which are composed of DNA and protein. Full virion particles contain a total of 12 adenosomes, each of which is found below one vertex of the icosahedral capsid. (Courtesy J. Brown and W. Newcomb, University of Virginia.)

Figure 32-5 Adenovirus causing necrotizing pneumonia. Focal necrosis is apparent; the prominent cell in the center of the field is an adenovirus-infected "smudge cell," with an enlarged nucleus with basophilic inclusions surrounded by a thin rim of cytoplasm (H&E, $\times 80$ original magnification). (Courtesy William D. Travis, MD, Memorial Sloan Kettering Cancer Center, New York, NY.)

Figure 32-6 Graph showing comparison of the clinical characteristics of acute respiratory disease (ARD) of military recruits and pharyngoconjunctival fever of civilians. (Adapted from Dascomb HE, Hilleman MR: Clinical and laboratory studies in patients with respiratory disease caused by adenoviruses. *Am J Med* 21:161–174, 1956, and Martone WJ, Hierholzer JC, Keenlyside RA, et al: An outbreak of adenovirus type 3 disease at a private recreation center swimming pool. *Am J Epidemiol* 111:229–237, 1980.)

viruses and therefore, when present, is a useful diagnostic finding in adenovirus respiratory disease. With adenovirus respiratory disease, the conjunctivitis is typically mild and follicular, although some adenovirus types also cause the more severe condition, epidemic keratoconjunctivitis. Fever, chills, myalgia, and prostration are prominent features of adenovirus infection, so it is often perceived by the patient as a "flu-like" illness or an unusually severe cold.

Cases of acute respiratory disease tend to have more tracheobronchitis, perhaps reflecting acquisition of infection by the airborne route. Conversely, in pharyngoconjunctival fever, the infrequency of cough and other tracheobronchial complaints in some outbreaks may reflect infection contracted by pharyngeal and/or conjunctival inoculation with virus from contaminated water. The two syndromes are associated with the same viral serotypes and, in civilian

populations, both can be seen as sporadic cases. In young children, adenovirus infection has been associated with both mild and febrile respiratory illness, with an associated otitis media in approximately 40% of these cases.

Adenovirus Pneumonia. Adenovirus was first recognized as a cause of viral pneumonia in military recruits and has since been recognized as a rare cause of pneumonia in civilian adults (eFig. 32-5) and children. The clinical characteristics of adenovirus pneumonia are similar to those of other pneumonias, so it is difficult to make an accurate etiologic diagnosis on the basis of clinical features. In fatal cases, there has been extensive pulmonary damage, with death intervening 2 to 3 weeks into the illness. Intravascular coagulopathy has also been a late feature of some cases, and a septic shock picture has been described.²³ Adenoviruses cause a particularly aggressive form of pneumonia in neonates, characterized by necrotizing bronchiolitis and alveolitis.²⁴ The virus may be acquired from the mother, perhaps via the birth canal. Long-term sequelae of adenovirus infection may include persistent radiographic abnormalities, abnormal pulmonary function tests, bronchiectasis, and bronchiolitis obliterans.

Adenovirus Infection in Persons with Impaired Immunity. Adenoviruses can cause fatal pneumonia and disseminated infection, with hepatitis, hemorrhagic cystitis, and renal failure, in transplant patients and other immunodeficient persons.²⁵ Various immunotypes have been recovered from these patients (eTable 32-1), including higher numbered serotypes that are only seen in such patients. Types seen with particular frequency include 1, 2, 5, 6, 7, 11, 21, 31, 34, and 35. The clinical importance of the recovery of an adenovirus from these patients, particularly from stool samples, is often difficult to determine, because immunodeficient patients may shed adenoviruses in the absence of overt disease caused by them.

Diagnosis

Although diagnosis was traditionally achieved by virus culture, viral antigens or nucleic acid can be detected directly from appropriate specimens of respiratory secretions, conjunctival swabs, stool, or urine, depending on the clinical syndrome. Rapid detection of viral antigens in clinical specimens by ELISA or immunofluorescence and of viral DNA by nucleic acid amplification techniques is increasingly used instead of viral culture because of the fastidiousness of some serotypes and slow rate of isolation^{25a} (see Chapter 17). Quantitative measurement of adenovirus DNA levels in plasma may be useful for diagnosis and response to therapy.²⁶

Frozen specimens (-70°C) are satisfactory for testing because of the relative stability of adenoviruses. In cell culture, cytopathic effect usually appears in 3 to 7 days but may take several weeks, thus limiting the utility of viral culture in guiding clinical management. The time required to detect virus in cell culture can be shortened to as little as 2 days by employing centrifugation culture systems. Serodiagnosis has relied primarily on testing for a group-specific complement-fixation antibody response, using acute and convalescent serum specimens; however, infection with some adenovirus types is not detected by the

complement-fixation test. In biopsy specimens, the appearance of characteristic intranuclear basophilic inclusion bodies seen by light microscopy or of crystalline arrays of virus seen by electron microscopy is useful in histopathologic diagnosis.

Treatment and Prevention

Antiviral treatment of adenovirus infection does not have proven value. Ganciclovir and cidofovir are active in vitro, and an increasing number of reports indicate that intravenous ganciclovir may be useful in seriously ill patients, although at the expense of significant renal toxicity.²⁷ Cidofovir has also been used for treatment and for presumptive therapy of adenovirus infection in high-risk immunocompromised patients.²⁸ Although intravenous ribavirin (which is active for group C adenoviruses in vitro)²⁹ or ribavirin combined with immunoglobulin³⁰ has been used in individual patients, failures are common.³¹

Because of the prominent fever and systemic complaints associated with adenovirus respiratory disease, analgesics, such as aspirin and acetaminophen, are needed more often than with a milder coryzal illness such as a rhinovirus cold. Warm saline gargles are helpful for relieving throat pain, which does not usually require narcotics. The presence of pharyngeal exudate may sometimes lead to an incorrect diagnosis of streptococcal pharyngitis, resulting in the initiation of antimicrobial therapy.

Effective and safe live oral vaccines for adenovirus types 4 and 7 were developed for military use and, when delivered in enteric-coated capsules, have controlled acute respiratory disease in recruit populations. Use of these vaccines was not associated with replacement by nonvaccine serotypes. When manufacturing of these vaccines was discontinued, adenoviruses reemerged as important causes of acute respiratory disease in this population. A new vaccine for Ad4 and Ad7 has subsequently been introduced.³²

CORONAVIRUSES

Coronaviruses are enveloped viruses containing a single-stranded, positive-sense *ribonucleic acid* (RNA) genome of approximately 29,000 nucleotides. Distinctive club-shaped projections are present on the virus surface, giving the appearance of having a crown or corona, from which it derives its name. Coronaviruses are classified into four genera: alpha, beta, gamma, and delta. The beta genus is further subdivided into four lineages, A-D. The human coronavirus strains 229E (HCoV 229E) and HCoV NL63 are members of the alpha genus, while the human strains HCoV OC43 and HKU1 are members of the beta genus. The novel coronaviruses, SARS-CoV and MERS-CoV, are also members of the beta genus, in lineages B and C, respectively.³³

The virus contains five structural proteins: *spike* or S protein, *hemagglutinin-esterase* (HE), M (*matrix*), E (*envelope*), and N (*nucleocapsid*). The spike protein is the major envelope glycoprotein and mediates both attachment to cells and fusion with the cell membrane; antibodies to the spike protein are thought to be associated with protection and thus are candidates for therapeutic and vaccine targets. The second envelope protein, HE, is only found in some coronavirus strains. Nonstructural proteins such as the

viral replicases and proteinases, particularly the 3C-like proteinase, are also antiviral drug targets.

Epidemiology and Transmission

Human coronaviruses OC43 and 229E have been recognized as causes of the common cold for many years and cause frequent reinfections throughout life. In adults, these viruses account for 4% to 15% of acute respiratory disease annually and up to 35% during peak periods. Annual illness rates in children reach 8%, with peak rates up to 20%.³⁴ When *polymerase chain reaction* (PCR) techniques were applied to samples collected over 20 years from children younger than 5, coronaviruses were associated with 11.4 lower respiratory tract episodes and 67.3 upper respiratory tract illnesses per 1000 person-years.³⁵ The reported frequency of infection in adults for 229E and OC43 viruses has ranged from 15 to 25 per 100 persons per year, with up to 80% of infections seen in persons with prior antibody to the infecting virus.³⁶ Coronaviruses usually circulate during winter and early spring but can be detected year-round.³⁷

Novel coronaviruses have recently been associated with severe respiratory disease in outbreaks around the world. SARS emerged in southern China in 2003 and quickly spread globally.³⁸ The causative virus was subsequently named SARS-CoV. Ultimately, at least 8098 probable cases of severe respiratory disease and 774 deaths in all ages were attributable to SARS worldwide before the outbreak terminated in 2004. The source of this outbreak is believed to have been from an animal reservoir, the civet cat. More recently, a second outbreak of coronavirus severe respiratory illness has been recognized, with cases primarily found in Middle Eastern countries.^{39,39a,39b} In May 2014, the first case of MERS was confirmed in a traveler from Saudi Arabia to the United States. A second case was identified in a traveler from Saudi Arabia to Florida. The two cases were not linked.^{39c} The virus responsible for MERS has been named MERS-CoV. It is genetically closely related to coronaviruses found in bats, and evidence indicates that MERS-CoV also infects camels, but the role of each of these in transmission to humans remains to be defined.^{40,41} Information on MERS-CoV is actively evolving; current information can be found at <http://www.cdc.gov/coronavirus/mers/>.

For all coronaviruses, transmission likely involves close contact and inoculation of the respiratory tract with infectious secretions via large droplets as demonstrated in human challenge experiments for OC43⁴² and animal studies for SARS-CoV.⁴³ For SARS-CoV, virus shedding peaked at day 10 of symptom onset, which was at the height of disease severity.⁴⁴ This phenomenon accounted for the preponderance of transmission in hospitals, a feature that allowed the outbreak to be controlled with infection control procedures. The incubation period for SARS is estimated from 2 to 10 days, and for conventional human coronaviruses 3 to 4 days.

Pathogenesis

Conventional coronavirus antigen has been detected in epithelial cells shed from the nasopharynx of infected volunteers⁴⁵ and, during experimental infection, nasal airway resistance, mucosal temperature, and the albumin content of nasal secretions increase.⁴⁶ However, relatively little is

known about the pathogenesis of the common cold induced by conventional human coronaviruses.

The hallmark of pulmonary pathology in fatal cases of SARS was diffuse alveolar damage,⁴⁷ type II pneumocyte hyperplasia, squamous metaplasia, and multinucleated giant cells. Hemophagocytosis, or the phagocytosis of erythrocytes, leukocytes, and platelets by histiocytes, was reported, potentially as a consequence of cytokine dysregulation.⁴⁸ Furthermore, virus was detected within pulmonary epithelial cells.⁴⁹ From these findings, it is postulated that disease pathogenesis involves both direct damage to pulmonary epithelia by the virus in combination with an excessive or dysregulated host immune response.

Clinical Illness

Conventional human coronaviruses produce a typical coryzal illness that is indistinguishable from colds due to other viruses. Coronaviruses have also been linked with acute otitis media, exacerbations of asthma in children, and with exacerbations of chronic bronchitis and pneumonia in adults.

In contrast, SARS has a nonspecific presentation that is difficult to distinguish from other viral acute respiratory illnesses, particularly influenza. Common symptoms on presentation are fever, chills and/or rigors, myalgias, and occasionally diarrhea. Cough and dyspnea are the predominant respiratory symptoms but may not be present initially. Respiratory disease becomes more severe over 4 to 7 days, and about 20% of patients require respiratory support. MERS has had a similar presentation, although GI symptoms may be more prominent.⁵⁰ SARS fatality rates were 9.6% for all ages but higher in older adults,⁵¹ and children had milder disease.⁵² Similarly, the majority of recognized cases of MERS to date have been in individuals with comorbidities.⁵³ SARS laboratory abnormalities include elevations in lactate dehydrogenase, transaminases, and creatine kinase, as well as hematologic abnormalities, particularly lymphopenia (depletion of CD4 and CD8 T cells) and thrombocytopenia.

Diagnosis

Common findings on chest CT include unilateral or bilateral areas of ground-glass opacifications and interlobular septal and intralobular interstitial thickening. In most patients, peripheral involvement in the lower lung zones has been observed. In some cases, after recovery from acute illness, pulmonary fibrosis has developed.⁵⁴ Clinical features predictive of poor outcomes included the presence of bilateral disease at presentation, markedly elevated lactate dehydrogenase, older age, and other comorbid conditions.

The main site of viral replication of SARS-CoV appears to be the lower respiratory tract.⁴⁹ PCR detection is most reliable in the sputum, but viral RNA can also be detected in the blood and stool.⁵⁵ Serum antibodies rise within 2 to 3 weeks of illness, although measurements at 4 weeks have become the standard to exclude SARS.

Treatment and Prevention

Immunity against coronaviruses appears to be short-lived. Epidemiologic studies of coronavirus infection have demonstrated high reinfection rates.⁵⁶ In human volunteer experiments, infection with a 229E-like coronavirus only induced

effective immunity short-term because rechallenge with homotypic virus, the 229E serotype, resulted in infection and illness.⁵⁷ In addition, under certain circumstances, vaccines against animal coronaviruses have led to enhanced disease.⁵⁸ This is being taken into consideration but is not deterring efforts to develop an efficacious SARS-CoV vaccine.⁵⁹

There are no currently available antiviral agents with demonstrated clinical activity against coronaviruses in humans. Agents with potential activity against SARS-CoV include chloroquine, protease inhibitors, ribavirin, type I interferons, niclosamide, and anti-inflammatory agents such as indomethacin.⁶⁰⁻⁶² Ribavirin in combination with lopinavir/ritonavir (protease inhibitors used in HIV disease) was associated with a lower incidence of adverse outcomes compared with historical controls of ribavirin alone in one study. Nelfinavir, another protease inhibitor, has also demonstrated in vitro antiviral activity. Other targets for controlling SARS viral replication have included interferons. Although the mechanisms are unknown, chloroquine, niclosamide, and indomethacin all inhibit SARS-CoV in vitro.⁶³⁻⁶⁵

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is a member of the gammaherpesvirus subfamily of the herpes viruses and has the same structural and biochemical characteristics, which include an internal core containing linear double-stranded DNA, an icosahedral capsid containing 162 capsomeres, and an envelope derived from the host-cell nuclear membrane. However, the large size of the CMV virion (200 nm) and larger genome (>200,000 bp) distinguish it from other human herpes viruses. There is approximately 80% homology between the genomes of various strains of CMV, but sufficient differences exist to permit strain identification by restriction endonuclease analysis. The CMV genome codes for approximately 33 structural proteins, the functions of many of which are currently unknown. In addition, clinical isolates often encode multiple gene products not seen in laboratory strains. Envelope glycoproteins B and H have been identified as major antigens eliciting neutralizing antibody. Glycoprotein B may also be a target for cytotoxic T lymphocyte responses,⁶⁶ while multiple proteins also serve as targets for T-cell responses. CMV-specific, cytotoxic T-cell responses are an important host defense mechanism that is associated with survival from CMV infection in bone marrow transplant recipients.⁶⁷ However, CMV uses multiple mechanisms, including down-regulation of HLA class I on the cell surface and interference with antigen processing, to evade recognition by the host.

Epidemiology and Transmission

Infection with CMV, whether symptomatic or not, is followed by prolonged excretion of virus in urine, saliva, stool, tears, breast milk, vaginal secretions, and semen. Thus, the major reservoir for CMV is asymptomatic infected persons. Virus shedding persists for years in children with congenital and perinatal CMV infections. The virus is believed to be transmitted by direct contact, especially under conditions of intimacy such as found in child care centers⁶⁸ and the family setting. Thus, the rate of acquisition of infection is

greater in populations with high density, leading to infection at an early age. In addition to transmission by sexual intercourse, passage through a contaminated birth canal, and ingestion of breast milk, CMV infection can be acquired from transfused blood products and from transplanted organs. No seasonal patterns of CMV infection have been observed.

Pathogenesis

In human fibroblast cell cultures, CMV produces a slowly progressive lytic infection. Infected cells contain large irregular basophilic intranuclear inclusions and also eosinophilic inclusions in paranuclear areas. The intranuclear inclusions are a hallmark of CMV infection and have been found in cells of a number of organs, including kidney, liver, and the GI tract, as well as the lung (Fig. 32-7). In the lung, fibroblasts, epithelial cells, endothelial cells, and smooth muscle cells are all targets for CMV infection.⁶⁹

In immunocompetent persons, most infections are subclinical. If symptoms arise, the most typical manifestation is that of acute pharyngitis with features similar to mono-

nucleosis. In immunocompromised hosts, there may be a variety of clinical syndromes, the severity of which is impacted by whether infection is acquired *de novo* or represents reactivation of endogenous virus. The risk of severe disease is particularly high in transplant patients when a CMV-seronegative recipient receives an organ from a seropositive donor.

The pathogenesis of CMV pneumonia is partly related to viral replication but also thought to have an immunopathologic basis.⁷⁰ The development of CMV pneumonitis reflects a complex interaction between viral infection and graft-versus-host disease, particularly in marrow transplant recipients^{71,72,72a} (see Chapter 91). Two patterns of histopathology have been described in the lung tissue of bone marrow transplant patients with serious pneumonia.⁷³ One is a military pattern, with multiple focal lesions showing extensive cytomegaly with localized necrosis, alveolar hemorrhage, fibrin deposition, and neutrophilic response (see Fig. 32-7). The other is an interstitial pattern, with alveolar cell hyperplasia, interstitial edema, lymphoid infiltration, and diffusely distributed cytomegalic cells.

Clinical Illness

Cytomegalovirus causes a variety of human diseases, including congenital and perinatal infections, infectious mononucleosis, hepatitis, posttransfusion infection, and invasive infection in patients with impaired immunity. In transplant populations, CMV infection often involves multiple organ systems in conjunction with other opportunistic infectious agents.

Because the virus rarely causes pneumonia in healthy hosts, the main impact of CMV as a respiratory pathogen is in immunocompromised patients. In recipients of allogeneic bone marrow transplants, CMV is the most common infectious cause of interstitial pneumonia and, if untreated, is responsible for the highest fatality rate. The risk of CMV pneumonia is greatest between 30 and 90 days after bone marrow transplant. However, late-onset CMV syndromes, at more than 180 days posttransplantation, have been increasingly recognized with effective control of earlier-onset disease.

Risk factors for the disease include advanced age, the presence of acute graft-versus-host disease, intensive conditioning regimens, and allografts. CMV infection and pneumonitis also develop in the majority of lung transplant recipients who are seronegative and, if infection develops in a single-lung recipient, disease is especially marked in the transplanted lung.⁷⁴ In these patients, CMV pneumonitis may be a factor in the development of bronchiolitis obliterans. CMV can also be a primary pathogen in persons with AIDS, although it is more often encountered in conjunction with other pulmonary pathogens^{74a} (see Chapter 90). Characteristically, patients with CMV pneumonia have sustained fever, nonproductive cough, and dyspnea. Rales and tachypnea are often present, and marked hypoxemia is an indicator of life-threatening infection. Pneumonitis may be accompanied by mild neutropenia, thrombocytopenia, and elevated liver enzymes, which may be helpful in differential diagnosis.

Recently, CMV reactivation has been demonstrated to play a role in critically ill, previously immunocompetent patients. During the critical illness, some evidence suggests

Figure 32-7 Cytomegalovirus infection. **A**, CMV pneumonitis with mild alveolar wall thickening and hyperplastic type II pneumocytes, some of which are infected, showing cytomegaly, nucleomegaly, thickened basophilic nuclear membranes and nuclear inclusion and small basophilic cytoplasmic inclusions (hematoxylin and eosin x80 original magnification). **B**, CMV pneumonitis with infected cells highlighted by immunohistochemistry with a brown color (CMV immunohistochemistry, x40 original magnification). (Images courtesy William D. Travis, MD, Memorial Sloan Kettering Cancer Center, New York, NY.)

a transient and vulnerable period of “immunoparalysis,” making reactivation and not exogenous infection of CMV more likely. In these patients, CMV viremia was found in 33% and was associated with prolonged hospitalization and death.⁷⁵ It is currently unclear whether CMV prophylaxis would be beneficial in this setting.

Diagnosis

Cytomegalovirus pneumonia should be in the differential diagnosis for any immunosuppressed patient with unexplained lower respiratory complaints or pulmonary opacities. However, the clinical assessment of patients with suspected CMV pneumonia is complicated because there are often simultaneous pulmonary infections with other microbes^{76,77} and because the clinical features and radiographic appearance of CMV pneumonia are not sufficiently characteristic to permit an accurate etiologic diagnosis. In addition, noninfectious pulmonary conditions are also common in the population at risk for CMV pneumonitis, including pulmonary malignancy or hemorrhage and post-transplant lymphoproliferative disorder (see eFigs. 91-16 and 91-17).

Chest radiographic changes (see eFig. 91-5A) are usually bilateral, with diffuse or focal haziness involving the mid and lower lung fields. Both miliary and interstitial radiographic patterns have been described. Patients with a miliary pattern may have a sudden onset of tachypnea, severe respiratory distress, and hypoxemia resulting in a rapidly fatal course,⁷⁸ whereas patients with an interstitial pattern of disease often have an insidious onset of pneumonia with slowly progressive hypoxemia. In these patients, pulmonary opacities may be initially localized, with bilateral spread over days or weeks. Often the perihilar distribution of the opacity is suggestive of pulmonary edema.⁷⁴ Common chest CT scan findings include small nodules (see eFigs. 91-3B, 91-4, 91-5), consolidation (see eFig. 91-2), and ground-glass attenuation (see eFigs. 91-3 and 91-5).⁷⁹

In patients with possible CMV pneumonia, the preferred approach to diagnosis is quantitative PCR in serum or *bronchoalveolar lavage* (BAL) fluid.⁸⁰ Culture and pathologic examination of specimens obtained by BAL and transbronchial biopsy may also be diagnostic, although these specimens are less suitable for making management decisions in acutely ill patients. The detection of virus in respiratory secretions, urine, or blood does not establish with certainty that CMV is responsible for a particular clinical syndrome. This is particularly true in patients with AIDS, in whom detection of CMV in BAL is often not associated with pulmonary pathology. However, in transplant recipients, the presence of CMV in blood does increase the risk of subsequent development of CMV pneumonia and is used in guiding preemptive therapy. Serologic testing has no role in diagnosis of acute infection and is used only to determine the serologic status of donors and recipients before transplantation.

Treatment and Prevention

Once CMV pneumonitis is established, particularly in allogeneic bone marrow transplant patients, poor outcomes are common. Ganciclovir is highly active against CMV *in vitro*, but monotherapy is not effective in pneumonitis in bone

marrow/stem cell transplant recipients. The combination of ganciclovir therapy and intravenous CMV immune globulin⁸¹ can reduce mortality from approximately 90% to 50% or lower in these patients. The effect of the immune globulin in this situation may mostly be to ameliorate graft-versus-host disease. Whether combination therapy is required in solid organ transplant recipients with CMV pneumonia is uncertain. Cidofovir and foscarnet are other antiviral drugs with activity against CMV. Both have been used successfully to treat CMV retinitis, but their effectiveness for treating CMV pneumonia has not been established. All of the available CMV antivirals have the potential for serious side effects that require close monitoring.

Guidelines for reducing the risk of CMV disease in stem cell transplant recipients have been published.⁸² Transplant candidates should be screened for evidence of CMV immunity, and CMV-seronegative recipients of allogeneic stem cell transplants from CMV-seronegative donors should receive only leukocyte-reduced or CMV-seronegative RBCs and/or leukocyte-reduced platelets. In mismatched solid organ transplant recipients (seronegative recipient/seropositive donor), posttransplant prophylaxis with oral ganciclovir or its prodrug valganciclovir significantly reduces the risk of CMV disease, although late-onset disease still happens.⁸³ Another strategy is preemptive therapy with ganciclovir or another anti-CMV agent when screening detects infection, but before clinically detectable disease develops. This strategy requires the use of rapid, sensitive, and specific laboratory tests for diagnosis.

No vaccines are available for the prevention of CMV infection or disease, although several strategies are being actively pursued, including live attenuated and inactivated subunit vaccines.

HANTAVIRUSES

Hantaviruses are members of the Bunyavirus family and include a number of genetically diverse viruses. The hantavirus responsible for an outbreak of severe pulmonary disease in the southwestern United States, Sin Nombre virus, is roughly spherical, with a mean diameter of 112 nm. The virions contain a dense envelope, surrounded by fine surface projections. Filamentous nucleocapsids are present within the virions. The genome consists of negative-sense single-stranded RNA arranged in three physically discrete gene segments. The *smallest segment* (S) encodes the nucleoprotein, the *middle-sized segment* (M), the two envelope glycoproteins, G1 and G2, and the *largest* (L), the putative polymerase protein.⁸⁴

Viral entry into the cell is mediated by a variety of cell surface integrins,⁸⁵ which may be related to the patterns of pathogenicity of the virus. The genome is segmented, and genetic reassortments in dually infected cells are common. It is believed that new pathogenic strains arise by this mechanism.

Epidemiology and Transmission

The *hantavirus pulmonary syndrome* (HPS) is a zoonosis in which humans experience severe, often fatal disease. Each of the individual hantavirus strains appears to be associated with a specific rodent host (e.g., Sin Nombre virus with the deer mouse, Bayou virus with the rice rat, *Black Creek*

Canal virus (BCCV) with the cotton rat, and New York virus with the white-footed mouse). The rodent hosts experience prolonged asymptomatic infection, but the features that are associated with maintenance of these viruses in rodent populations and with rodent-to-rodent transmission are unclear. Serologic studies suggest that hantaviral infection of feral rodents is widespread throughout North America.⁸⁶

Transmission to humans is presumed to result from contact with infected rodent excreta. Hantaviruses are stable and can persist in the environment for 10 to 15 days without loss of viability.⁸⁷ Risk factors for acquisition of HPS include high densities of rodents in the household, cleaning of contaminated environments, agricultural activities, and other forms of occupational exposure to rodent droppings. In the Four Corners region of the southwestern United States, El Niño–southern oscillation events have been linked to increased rainfall, high rodent population densities, and increased numbers of cases of HPS.⁸⁸

Person-to-person transmission was not seen in the North American outbreaks.⁸⁹ In contrast, a recent outbreak of HPS in South America has suggested that, under certain circumstances, person-to-person transmission can take place.⁹⁰ This feature appears to be unique to the particular hantavirus implicated in that outbreak (Andes virus) and has not been a major component of other outbreaks. Currently, approximately 11 to 48 cases of HPS per year are reported in the United States,⁹¹ with a case fatality rate of 35%.

Pathogenesis

Infection with Sin Nombre virus or other agents of HPS have relatively long incubation periods (median 14 to 17 days; range 1 to 51 days),⁹² and antibody and cellular responses in humans are usually detectable at the time of presentation.⁹³ Neutralizing antibody is directed against the surface glycoproteins G1 and G2, and lower titers on presentation correlate with greater disease severity.⁹⁴ Viremia is detectable at presentation and declines promptly after resolution of fever.

Pathologic findings in fatal cases include pleural effusions, alveolar edema and fibrin, and interstitial mononuclear cell infiltrate⁹⁵ with little necrosis or neutrophil infiltration. These findings are felt to be most consistent with a capillary leak syndrome with subsequent noncardiogenic pulmonary edema. Immunopathologic responses play a major role in HPS.⁹⁶ Infection of humans with Sin Nombre virus and other hantaviruses results in widespread expression of viral antigens in endothelial cells of pulmonary and cardiac tissues,⁹⁷ and CD8 T cell responses peak at the time of maximal clinical symptoms, implicating these responses in the pathogenesis of disease.⁹⁸ Myocardial depression has also been ascribed to induction of nitric oxide and locally secreted cytokines in response to infection.⁹⁹ Another pathogenic mechanism may be antagonism of the host innate immune response by the hantavirus G1 tail.¹⁰⁰

Clinical Features

Presentation of HPS begins with a prodrome of fever, chills, and myalgias, occasionally accompanied by abdominal discomfort and GI symptoms, and generalized malaise. Upper respiratory symptoms are usually absent. After a variable

period of several days, the patient presents with a mild, nonproductive cough and progressive dyspnea resulting from leakage of high-protein edema fluid into the alveoli. On physical examination patients are febrile, with tachypnea and tachycardia with mild hypotension. Examination of the chest may reveal fine crackles but is otherwise unremarkable.

Laboratory studies generally reveal hemoconcentration, mild thrombocytopenia, and mildly elevated liver function tests. The triad of thrombocytopenia, left shift with circulating myeloblasts, and circulating immunoblasts is highly suggestive of HPS.¹⁰¹ Multivariate analysis has identified dizziness, nausea, and the absence of cough as clinical symptoms predictive of HPS, as well as thrombocytopenia, elevated hematocrit, and decreased serum bicarbonate as features that help distinguish HPS from other causes of acute respiratory distress such as pneumococcal pneumonia and influenza.¹⁰² Mild renal abnormalities may be detected but, unlike the situation with another hantaviral illness, hemorrhagic fever with renal syndrome, do not progress to renal failure. Renal dysfunction may be more common in HPS associated with the Bayou hantavirus.¹⁰³

Pleural effusions are present in most cases. Early in the course of HPS, these effusions are transudative, while later they develop higher fluid protein content and in severe cases have the protein characteristics of plasma.¹⁰⁴ Cardiopulmonary manifestations in severe cases include a shock state with low cardiac index, low stroke volume index, and high systemic vascular resistance.¹⁰⁴ Progression is associated with worsening cardiac dysfunction and development of lactic acidosis. In those patients who survive, exertional dyspnea and reduced expiratory flow are common in early convalescence and resolve in most patients.¹⁰⁵ However, some patients have manifested long-term pulmonary and cognitive dysfunction.¹⁰⁶

Diagnosis

Chest radiographs are typical of pulmonary edema, without consolidation. In the absence of immunodeficiency, patients universally have detectable serum *immunoglobulin M* (IgM) and IgG antibody at the time of admission, and serologic techniques are the mainstay of diagnosis. In low-prevalence areas, a positive IgM is diagnostic.¹⁰⁷ Virus can also be detected in blood by *reverse transcriptase polymerase chain reaction* (RT-PCR) during the first 10 days of illness.¹⁰⁸ In contrast, hantaviruses are difficult to isolate from clinical material in cell culture and grow slowly. Isolation of virus from tissue is laborious and time consuming and must be undertaken in suitable containment facilities, so it is not useful for diagnosis.

Treatment and Prevention

Treatment is supportive and requires careful management of fluid status to maintain perfusion without exacerbating pulmonary edema. It has been suggested that high-dose steroid therapy may be useful⁹⁶ because of the pathogenesis of the disease and potential utility of steroids in systemic capillary leak syndrome. In severe cases, extracorporeal membrane oxygenation may be beneficial.^{109,110} The broad-spectrum antiviral agent ribavirin is active against hantavirus in vitro and was demonstrated to be effective against hantavirus-induced hemorrhagic fever with renal

syndrome in Korea.¹¹¹ However, trials of ribavirin in HPS have not shown efficacy.¹¹²

HERPES SIMPLEX VIRUS

Both *herpes simplex virus* (HSV) types 1 and 2 belong to the alphaherpesvirus subfamily of herpesviruses and share the same basic structural features. HSV-1 is most commonly associated with respiratory infection, whereas HSV-2 is more commonly associated with genital infection. The two HSV types were originally differentiated by neutralization assay and have been found to differ in a number of biologic and biochemical properties as well. Infection with either type results in production of both type-specific and cross-reactive antibodies, with higher concentrations of antibodies being produced against the homologous type.

Epidemiology and Transmission

Humans are the reservoir for HSV-1 and HSV-2 viruses. With primary infection, infectious virus is produced in the skin and mucous membranes, being present in vesicle fluid and cellular debris from herpetic ulcers. After establishment of latency in nerve ganglia, virus is intermittently shed in respiratory, vaginal, and urethral secretions in the absence of clinical disease. Asymptomatic respiratory tract shedding can be detected in about 1% to 2% of seropositive children and adults.

HSV-1 spreads by means of transfer of virus-containing respiratory secretions, vesicle fluid, and cell debris under conditions of close personal contact. The portals of entry for primary infection are the mucous membranes of the oropharynx and possibly the eye. Virus deposited onto areas of burned or abraded skin, and exogenous inoculation or autoinoculation of virus, also lead to clinical lesions. Cases of HSV-1 arise sporadically throughout the year, occasionally in small clusters. HSV-1 infection is usually acquired in childhood or adolescence, with epidemiologic surveys showing a prevalence of antibody to HSV-1 in 30% to 100% in adults.

Pathogenesis

Primary HSV infection has a mean incubation period of approximately 1 week. Primary infection begins at a local site, with viral replication in parabasal and intermediate epithelial cells and resultant cell destruction and initiation of host inflammatory responses. Cells containing characteristic nuclear inclusions and sometimes multinucleation may be observed in lesions. In immunocompetent individuals, regional lymph nodes may be involved during primary infection, but the disease is usually contained at the primary site by innate antiviral responses. In neonates and others with deficient or impaired immune systems, local infection may be followed by viremic spread to multiple organs, including skin, liver, brain, adrenals, and lungs. Disease may also disseminate in such individuals following reactivation of latent infection. Visceral infection is characterized by a highly destructive coagulation necrosis of involved sites.¹¹³ In a series of fatal cases of HSV pneumonia, inflammatory infiltrates, parenchymal necrosis, and hemorrhage were found at autopsy.¹¹⁴ Patients with associated herpetic laryngotracheitis have necrotizing lesions in these areas.

Latent infection is established in sensory nerve ganglia and is followed by life-long recurrences of virus shedding and often lesions on skin and mucous membranes of the involved dermatomes. Cellular immunity is of primary importance in controlling HSV infection; studies in patients with AIDS and severe mucocutaneous HSV indicate that both CD4 and CD8 T cells contribute to control of viral replication and spread.¹¹⁵

Clinical Illness

Acute Gingivostomatitis and Pharyngitis. Herpetic disease of the oral cavity and pharynx is the most common overt manifestation of primary infection with HSV-1. Scattered or clustered vesicles and ulcers of various sizes (3 to 7 mm) are located on the buccal mucosa, tongue, gingiva, or floor of the mouth. Individual lesions usually appear as a shallow, white-based ulcer surrounded by a thin rim of erythema. Pain is prominent in involved areas of the mouth and pharynx, and regional nodes are tender and enlarged, particularly with the pharyngitis. Fever, malaise, and reduced oral intake may add to the overall severity of these illnesses, which last up to 2 weeks.

Chronic Ulcerative Pharyngitis and Laryngotracheitis. In immunocompromised patients, including those with AIDS, both primary and recurrent HSV infection may manifest as a chronic erosive process of the mucous membranes of the oral cavity and upper airway. Characteristically, the lesions appear as large (5 to 15 mm) individual ulcerations that are slowly progressive and may coalesce when present in adjacent sites. The base of the ulcer is white or gray. Although shallow, the lesions are usually painful and may reduce oral intake. Herpetic lesions are sometimes present on the lip and skin of the face. Infection may spread to the esophagus and lower airway, possibly facilitated by instrumentation such as orotracheal intubation or bronchoscopy, resulting in the development of similar lesions at these sites. Clinical features of herpetic tracheobronchitis include dyspnea, cough, fever, chills, diaphoresis, chest pain, wheezes, hypotension, and hypoxemia.¹¹⁶ Herpetic tracheobronchitis has also been reported in elderly patients presenting with bronchospasm who did not have histories of chronic lung disease or of immunosuppression.¹¹⁷

Pneumonia. Herpes simplex virus causes pneumonia in neonates with congenital and peripartum infections and in patients with malignancy, burns, organ transplantation, and other conditions associated with impaired immunity. Herpes simplex pneumonia has been reported in neonates between the third and 14th days of life and to be associated with prominent hila and central interstitial opacity on chest radiography.¹¹⁸ Other associated findings include thrombocytopenia, disseminated intravascular coagulation, abnormalities in liver function, vesicular skin lesions, and deterioration during antimicrobial treatment. The pathologic findings in infants, children, and adults suggest that the disease may be the result of direct extension of infection from the tracheobronchial tree to the lung or as the result of hematogenous dissemination of virus from mucocutaneous lesions of the upper airway or genitourinary tract. CT scan findings include multifocal segmental and subsegmental ground-glass opacities but are not

distinctive.¹¹⁹ In one study, more than one half of the patients had concomitant pulmonary infection with other microorganisms, including bacterial, candidal, and *Aspergillus* species and cytomegalovirus.¹¹⁴ Histologic evidence of herpetic esophagitis was present in 10 of 16 patients with herpes pneumonia in whom esophageal examination was performed. Some cases are nosocomially acquired.¹²⁰

Herpes simplex virus infection of the lower airway has also been found in association with ARDS. The relationship of HSV infection to ARDS is unclear, but the presence of HSV in the lower respiratory tract was associated with the need for prolonged respiratory support and an increased late mortality. Isolation of HSV from lower respiratory tract secretions has also been common in mechanically ventilated patients and may be associated with a poor outcome,^{121,122} although it is unclear whether this represents reactivation as a consequence of severe illness or whether the virus plays a direct role in mortality.^{123,124}

Diagnosis

The clinical features of herpetic gingivostomatitis are sufficiently characteristic to permit accurate diagnosis in most cases. Other conditions with similar oral lesions are limited and include herpangina, aphthous stomatitis, Steven-Johnson syndrome, and other enanthems resulting from infection and drug sensitivities. In herpangina, the lesions are smaller (1 to 3 mm), more often vesicular, and usually localized to the soft palate. The ulcers in aphthous stomatitis are few, relatively deep, and circumscribed. Aphthosis is characterized by periodic recurrence, whereas acute herpetic gingivostomatitis and pharyngitis are limited to a single occurrence. Herpetic pharyngitis, when exudative, must be distinguished from pharyngitis due to *Streptococcus pyogenes*, adenovirus, Epstein-Barr virus, and diphtheria. The diagnosis of acute herpetic disease of the oropharynx can be confirmed by examination of Giemsa- or Wright-stained smears of scrapings from the base of a fresh lesion (Tzanck test) and by culture of scrapings or swab specimens. Techniques for the rapid detection of viral antigens or DNA are widely available.

Chronic ulcerative pharyngitis due to HSV has a characteristic clinical appearance that is highly suggestive of the diagnosis. The white color of the lesions may lead to confusion with candidiasis, but the lesion of thrush is an easily removable plaque, not an ulcer. Thrush and chronic herpetic pharyngitis may coexist in the same patient. The lesions of aphthous stomatitis are not characteristically found in the back of the oropharynx and are relatively small (2 to 5 mm) with a fixed diameter.

The diagnosis of herpetic laryngotracheitis may be difficult because of the inaccessibility of the lesions. The disease should be suspected in any immunocompromised patient with herpetic lesions of the mouth, upper airway, or skin of the face, especially if endotracheal intubation has been performed. In such patients, bronchoscopic examination is indicated for sampling of suspected areas for cytology and viral culture.

The diagnosis of HSV pneumonia should be suspected in any immunocompromised patient with unexplained pulmonary opacities, especially in the presence of herpetic laryngotracheitis or herpetic lesions of other mucocutaneous sites, including the genital area. Definitive diagnosis of

HSV pneumonia depends on obtaining a sample of involved lung for viral culture and testing for HSV antigen or nucleic acid. Limited experience with lung biopsy in patients with HSV pneumonia suggests that obtaining adequate samples for culture and histologic examination may be a problem¹¹⁴ and that, when possible, generous biopsy specimens should be obtained.

Treatment and Prevention

No vaccines of proven value are currently available. Primary HSV gingivostomatitis in immunocompetent persons responds to oral acyclovir treatment. Specific therapy of herpes simplex pneumonia has not been evaluated in controlled trials, but most clinicians would use intravenous acyclovir. In immunosuppressed patients with chronic mucocutaneous HSV infection, including pharyngitis and laryngotracheitis, prompt treatment with acyclovir is recommended to control the local infection and prevent possible dissemination to the lung. Valacyclovir, the valine ester prodrug of acyclovir, and famciclovir, the prodrug of penciclovir, are orally administered drugs that are also effective for mucocutaneous HSV.

Antiviral susceptibility testing should be considered in patients with serious HSV infection who do not respond to initial treatment with oral valacyclovir or intravenous acyclovir. Foscarnet is probably the best available alternative therapy. Prophylactic intravenous and oral acyclovir regimens have been shown to be effective in preventing recurrences of mucocutaneous HSV infection in seropositive patients undergoing intense periods of immunosuppression, such as bone marrow transplant recipients or patients receiving combination chemotherapy for leukemia.

INFLUENZA VIRUS

Influenza viruses belong to the family Orthomyxoviridae and are classified into three distinct types: influenza A, influenza B, and influenza C virus. All three viruses share the presence of a host cell-derived envelope, envelope glycoproteins important for entry and egress from cells, and a segmented negative-sense, single-stranded RNA genome. The standard nomenclature for influenza viruses includes the influenza type, place of initial isolation, strain designation, and year of isolation. For example, an influenza A virus isolated from a patient in Puerto Rico in 1934 is given the strain designation A/Puerto Rico/8/34.

The envelope glycoproteins are the *hemagglutinin* (HA) and *neuraminidase* (NA). HA mediates binding of the virus to sialic (also known as *neuraminic*) acid residues on host cell glycoproteins and glycolipids and is essential for viral entry. NA cleaves terminal sialic acid (neuraminic acid) residues from host cell molecules, thereby releasing new viral particles from the cell in which they replicated. At least 16 highly divergent, antigenically distinct HAs (H1 to H16), and at least 9 distinct NAs (N1 to N9), have been described in influenza A viruses. Influenza A viruses are therefore further divided into subtypes on the basis of the *hemagglutinin* (H) and *neuraminidase* (N) (e.g., H1N1 or H3N2). Infection with influenza virus results in long-lived resistance to reinfection with the homologous virus. Infection induces both systemic and local antibodies, as well as cellular

responses, each of which plays a role in recovery from infection and resistance to reinfection.

Epidemiology and Transmission

Influenza virus infection is acquired by transfer of virus-containing respiratory secretions. Both small particle aerosols and droplets probably play a role in this transmission, but for infection control purposes influenza is generally considered to be transmitted by droplets. In temperate climates in either hemisphere, epidemics are seen almost exclusively in the winter months (generally October to April in the Northern hemisphere and May to September in the Southern hemisphere), whereas in the tropics, influenza may be seen throughout the year.

Influenza epidemics are regularly associated with morbidity and mortality, usually expressed in the form of excess rates of pneumonia and influenza-associated hospitalizations and deaths, with as many as 51,000 deaths annually in the United States.¹²⁵ Attack rates are generally highest in the young, whereas mortality is generally highest in the elderly. Excess morbidity and mortality are particularly high in those with medical conditions including pulmonary conditions such as asthma or COPD. Rates of influenza-related hospitalizations are particularly high in healthy children younger than 2, where rates approach those of older children with high-risk conditions.^{126,127}

A high frequency of antigenic variation is a unique feature of influenza virus that helps explain why this virus continues to cause epidemic disease. Antigenic variation principally involves the two external glycoproteins of the virus, the HA and NA, and is referred to as antigenic drift or antigenic shift, depending on whether the variation is small or great. Antigenic *drift* refers to relatively minor antigenic changes that result from amino acid changes in one or more of the five identified major antigenic sites on the HA molecule.¹²⁸ Antigenic *shift* refers to the complete replacement of the HA or NA with a novel HA or NA. These viruses are “new” viruses to which the population has no specific immunity. When such a new virus is introduced into a population, a severe, worldwide epidemic, or pandemic, of influenza can result. Influenza pandemics in the 20th century include the H1N1 pandemic of 1918, the H2N2 pandemic of 1957, and the H3N2 pandemic of 1968. Extensive surveillance and sequence information suggests that these new HA and NA genes are introduced into viruses circulating in humans from resident populations of influenza A viruses in birds.¹²⁹

Since 1997, sporadic outbreaks of influenza in humans caused by direct transmission of avian viruses from bird to human have been reported. Although sustained human-to-human transmission has not been seen, avian subtypes such as H5N1¹³⁰ and H7N9¹³¹ continue to pose a potential pandemic threat. In the spring of 2009, a novel H1N1 virus containing genes from viruses of swine, avian, and human origin emerged. Importantly, the HA gene of this virus was derived from swine influenza virus. Although still an H1N1 virus, the novel, or *pandemic H1N1* (pH1N1) was antigenically distinct from the human H1N1 viruses in circulation since 1977. Instead, the HA was closely related to human H1 viruses from the early 20th century that had been introduced into pigs in approximately 1918 and had not undergone significant antigenic evolution in these animals since

that time. Perhaps for this reason, older adults were relatively spared, and the pandemic disease affected mainly children, adolescents, and adults younger than 50.

Although the circulation of multiple antigenic subtypes is confined to influenza A viruses, influenza B viruses undergo significant antigenic variation as well. Currently, two antigenically distinct lineages of influenza B have co-circulated, designated the “Yamagata” and the “Victoria” lineages. Because antibodies to viruses in one lineage do not provide substantial protection against the other, recent influenza vaccines have included examples of both (see later).

Pathogenesis

Infection with influenza virus in humans is generally limited to the respiratory tract. After inoculation, the incubation period is thought to be from 18 to 72 hours depending in part on the inoculum dose. Virus shedding is maximal at the onset of illness and may continue for 5 to 7 days or longer in children. In immunocompromised patients, especially recipients of solid organ or hematopoietic stem cell transplants, viral shedding can be prolonged for weeks to months.¹³²

Bronchoscopy of individuals with influenza typically reveals diffuse inflammation of the larynx, trachea, and bronchi, as well as a range of histologic findings, from vacuolization of columnar cells with cell loss, to extensive desquamation of the ciliated columnar epithelium down to the basal layer of cells.^{133,134} Generally, the tissue response becomes more prominent as one moves distally in the airway. Recovery is associated with rapid regeneration of the epithelial cell layer and pseudometaplasia. Fatal influenza pneumonia exhibits diffuse alveolar damage with hyaline membranes lining the alveoli, and the alveolar air spaces contain edema fluid, strands of fibrin, desquamated epithelial cells, and inflammatory cells (Fig. 32-8A-D).

Abnormalities of pulmonary function are frequently demonstrated in otherwise healthy, nonasthmatic young adults with uncomplicated (non-pneumonic) acute influenza. Demonstrated defects include diminished forced expiratory flow rates, increased total pulmonary resistance, and decreased density-dependent forced expiratory flow rates consistent with generalized increased resistance in airways less than 2 mm in diameter,^{135,136} as well as increased responses to bronchoprovocation.¹³⁵ In addition, abnormalities have been seen in the carbon monoxide diffusing capacity¹³⁷ and the alveolar-arterial oxygen difference.¹³⁸ Pulmonary function defects can persist for weeks after clinical recovery. Influenza in asthmatics or patients with chronic obstructive disease with influenza may result in acute declines in forced vital capacity or FEV₁. Individuals with acute influenza may be more susceptible to bronchoconstriction from air pollutants such as nitrates.¹³⁹

Clinical Illness

Typical uncomplicated influenza often begins with an abrupt onset of symptoms after an incubation period of 1 to 2 days. Systemic symptoms include feverishness, chilliness, or frank shaking chills, headaches, myalgia, malaise, and anorexia. Typical respiratory symptoms include dry cough, severe pharyngeal pain, and nasal obstruction and discharge. Elderly individuals may simply present with

Figure 32-8 Pulmonary involvement in 2009 H1N1 influenza. **A.** Acute necrotizing tracheitis and inflammation of the submucosal tracheal mucous glands (H&E, $\times 400$ original magnification). *Inset:* Immunohistochemical stain for influenza. Viral antigen is stained red-brown on a hematoxylin-stained background, with prominent staining of the respiratory epithelium and underlying mucous glands. **B.** Postmortem lung section showing diffuse alveolar damage with hyaline membranes (*arrow*) lining an alveolar duct and adjacent alveoli. The alveolar air spaces contain edema fluid, strands of fibrin, desquamated epithelial cells, and inflammatory cells (H&E, $\times 100$ original magnification). **C.** Massive infiltration of neutrophils in the airspaces of alveoli associated with secondary bacterial bronchopneumonia (H&E, $\times 100$ original magnification). *Inset:* Brown and Hopps modified tissue Gram stain showing chains of bacteria morphologically compatible with streptococci or pneumococci (*arrow*) ($\times 1000$ original magnification). **D1,** Immunohistochemical staining for influenza in bronchus. Viral antigen is stained red-brown on a hematoxylin and eosin-stained background. *Arrow* shows influenza antigen-positive cells in the bronchial epithelium. **D2,** The section shows an acute necrotizing bronchitis with transmural infiltration of inflammatory cells ($\times 100$ original magnification). **D3** and **4,** Immunohistochemical staining for influenza in a bronchiole. Influenza antigen-positive cells are seen in the bronchiolar epithelium, including ciliated cells, and in the nuclei of some basilar cells ($\times 400$ original magnification). Immunohistochemical staining for influenza in alveolar cells, both type I (**D3**) and type II (**D4**) ($\times 1000$ original magnification). (Adapted from Gill JR, Sheng ZM, Ely SF, et al: Pulmonary pathologic findings of fatal 2009 pandemic influenza A/H1N1 viral infections. *Arch Pathol Lab Med* 134(2):235–243, 2010. Fig 1).

fever, lassitude, and confusion without any of the characteristic respiratory complaints. There may be a wide range of symptoms, but the presence of fever plus either sore throat or cough is predictive of positive culture results for influenza in adults.

The syndrome of primary influenza viral pneumonia was first well documented in the 1957–1958 outbreak. The illness begins with a typical onset of influenza, followed by a rapid progression of fever, cough, dyspnea, and cyanosis. Physical examination and thoracic imaging studies reveal

bilateral abnormalities (Fig. 32-9, eFigs. 32-6 and 32-7), sometimes suggestive of an acute lung injury pattern or ARDS (eFig. 32-8). H1N1 (“swine-origin”) influenza infection has a relatively nonspecific appearance, ranging from normal or nearly normal chest radiography at presentation to multifocal bilateral opacities resembling multifocal pneumonia (eFig. 32-9) or a noninfectious acute lung injury pattern. Chest CT often shows multifocal areas of ground-glass opacity and consolidation, which may show a peripheral distribution, resembling organizing pneumonia

Figure 32-9 Seasonal influenza A. Frontal chest radiograph shows multi-focal, bilateral, perihilar, and lower lobe predominant bronchovascular thickening and somewhat nodular consolidation. (Courtesy Michael Gotway, MD.)

(eFig. 32-9B-E), although other patterns, including small nodules (eFigs. 32-10A and B), ground-glass opacity associated with linear and reticular abnormalities without a clear zonal distribution (eFig. 32-10C), and lobar consolidation (eFig. 32-10D), may be observed. Gram stain of the sputum fails to reveal significant bacteria, and bacterial culture yields sparse growth of normal flora, whereas viral cultures yield high titers of influenza A virus. Such patients do not respond to antibacterial drugs and the mortality is high.

Secondary bacterial pneumonia is an important complication of influenza (Fig. 32-8C) (eFig. 32-11). The classic description is of an influenza illness followed by a period of improvement, usually lasting 4 to 14 days. Recrudescence of fever is associated with symptoms and signs of bacterial pneumonia such as cough, sputum production, and an area of consolidation detected on physical examination and chest radiography. The most common bacteria implicated are *Streptococcus pneumoniae*, with a significantly increased frequency of *Staphylococcus aureus*,^{140,141} including methicillin-resistant *staphylococcus* (MRSA). Patients may present with mixed viral and bacterial pneumonia. Bacterial superinfections of influenza have been postulated as a major cause of death during the pandemic of 1918.¹⁴²

Patients with a wide range of preexisting conditions are well recognized to be at higher risk for the development of pneumonia and other complications of influenza leading to hospitalization or death (Table 32-4). In recent years, new conditions leading to increased risk have been recognized, including the presence of neuromuscular conditions that compromise respiration¹⁴³ and, in the 2009 pandemic, the presence of obesity.^{144,145} In addition, the 2009 pandemic reemphasized the known increased risk of hospitalization or death in women in all stages of pregnancy or in the immediate postpartum period.^{146,147}

Diagnosis

Immunologic detection of influenza antigens in respiratory samples can be used for rapid diagnosis, and a large number of such tests are commercially available^{147a} (see Chapter

Table 32-4 Target Groups for Influenza Immunization*

PERSONS AT INCREASED RISK FOR COMPLICATIONS

- All children aged 6 through 59 months
- All persons aged ≥ 50 years
- Adults and children who have chronic pulmonary (including asthma) or cardiovascular (except isolated hypertension), renal, hepatic, neurologic, hematologic, or metabolic disorders (including diabetes mellitus)
- Persons who have immunosuppression (including immunosuppression caused by medications or by HIV infection)
- Women who are or will be pregnant during the influenza season
- Children and adolescents (aged 6 months to 18 years) who are receiving long-term aspirin therapy and who might be at risk for experiencing Reye syndrome after influenza virus infection
- Residents of nursing homes and other long-term care facilities
- American Indians/Alaska Natives
- Persons who are morbidly obese (BMI ≥ 40)

PERSONS WHO CAN TRANSMIT INFLUENZA TO THOSE AT HIGH RISK

- Health care personnel
- Household contacts (including children) and caregivers of children aged ≤ 59 months (i.e., aged < 5 years) and adults aged ≥ 50 years, with particular emphasis on vaccinating contacts of children aged < 6 months
- Household contacts (including children) and caregivers of persons with medical conditions that put them at higher risk for severe complications from influenza

*Routine annual influenza vaccination is recommended for all persons aged ≥ 6 months who do not have contraindications.

Adapted from Summary Recommendations: Prevention and Control of Influenza with Vaccines: Recommendations of the Advisory Committee on Immunization Practices—(ACIP)—United States, 2013-14. Influenza Prevention and Control Recommendations <http://www.cdc.gov/flu/professionals/acip/2013-summary-recommendations.htm>

17). The reported sensitivities of each test in comparison to cell culture or nucleic acid amplification varies between 40% and 80% and depends on the nature of the samples tested and the viral strain. In general, sensitivities in adults and elderly patients tend to be lower than those reported in young children, who shed much larger quantities of virus and higher concentrations of antigen in their samples.¹⁴⁸ Similarly, sensitivity is likely to be higher early in the course of illness, when viral shedding is maximal.

Molecular diagnostic techniques have recently emerged as the diagnostic modality of choice in most laboratories. Real-time RT-PCR methods have been developed and licensed and are discussed in greater detail in Chapter 17. Many of these tests are designed to detect multiple respiratory pathogens simultaneously and are leading to a growing recognition of the role of respiratory viruses and coinfection in diverse respiratory infections.^{148a} Most cases of influenza, in otherwise healthy individuals with typical symptoms during the course of a recognized influenza epidemic, do not need specific viral confirmation. However, diagnostic testing should be used if the results of the test will influence subsequent clinical management, such as the use of antiviral agents, the need for antibacterial drugs, and the use of infection control.¹⁴⁹

Virus can also be isolated readily from nasal swab specimens, nasal aspirates, combined nose and throat swabs, sputum, or endotracheal aspirate specimens. More than 90% of positive influenza cultures can be detected within 3 days of inoculation.¹⁵⁰

Treatment and Prevention

Vaccines. Two types of vaccine are available for prevention of influenza. Inactivated vaccines consist of partially purified HA and NA preparations derived from virions produced in eggs or in cell culture or, in one case, purified recombinant HA produced in insect cells. Current vaccines contain one example of H1N1, one example of H3N2, and either one or both lineages of influenza B. Inactivated vaccines are administered intramuscularly or intradermally and are primarily designed to induce systemic antibody, although they also induce cellular immune responses that may be associated with protection. Inactivated vaccines are well tolerated in all age groups, although hypersensitivity to hens' eggs is a relative contraindication to use of egg-produced vaccines. Generally, if persons can eat eggs or egg-containing products, vaccination is safe. If necessary, individuals with anaphylaxis can be desensitized and safely vaccinated,¹⁵¹ or vaccines free of egg products can be used.

Increases in hemagglutination-inhibition antibody are seen in about 90% of healthy adult recipients of vaccine. Only a single dose of vaccine is required in individuals who have been previously vaccinated or who have experienced prior infection with a related subtype, but a two-dose schedule is required in unprimed individuals. This includes children up to age 9 who have not previously been vaccinated or who were vaccinated for the first time with only a single dose in the previous season.¹⁵² Diminished responses and diminished efficacy are seen in elderly and immunocompromised populations.

The protective efficacy of inactivated influenza vaccine is estimated to be in the range of 70% to 90% in healthy adults when there is a good antigenic match between vaccine and epidemic viruses.^{153,154} Few prospective trials of protective efficacy have been conducted in high-risk populations. In one placebo-controlled prospective trial, inactivated vaccine was approximately 58% effective in preventing influenza among adults older than 60 and 29% in those older than 70.¹⁵⁵ However, this study used a serologic definition of influenza infection, possibly biasing results in favor of vaccine efficacy.

Observational studies have suggested that in practice the effectiveness of inactivated vaccine in prevention of acute respiratory illness due to influenza ranges between 40% and 60%, with even lower effectiveness in older adults and in seasons with antigenic mismatch. Attempts to improve the effectiveness of inactivated vaccines have included the use of higher doses and adjuvants.

The live attenuated vaccine, administered intranasally, induces a limited, asymptomatic infection of the upper respiratory tract and induces a variety of immune responses designed to mimic the protective immunity induced by natural infection.^{156,157} The vaccine is well tolerated and highly effective in children but is associated with an increased frequency of wheezing in children younger than 2 years of age. Live vaccine is protective in adults as well, resulting in decreased laboratory-confirmed influenza in challenge studies and reduced frequencies of influenza-like illness in the field.¹⁵⁸ Although the vaccine is well tolerated in the elderly and in those with chronic lung disease, immune responses are less frequent in older recipients and the vaccine is not licensed for use in those older than 49.

Although vaccine virus can be recovered from vaccinated individuals, particularly children, for several days following vaccine, transmission is extremely unusual.¹⁵⁹ Live vaccine can be administered safely to health care workers except for those caring for immunosuppressed individuals requiring barrier precautions.

Randomized controlled comparisons of the efficacy of inactivated and live attenuated vaccine in children have consistently shown that live vaccine provides superior efficacy in this population, with an approximately 50% lower cumulative incidence of influenza in those receiving live vaccine.¹⁶⁰ Similar comparisons in adults have suggested slightly superior efficacy of inactivated vaccine,¹⁶¹ and large cohort studies are also consistent with the interpretation that inactivated vaccine has slightly better efficacy than live vaccine in adults, particularly in those who have received vaccines in previous years.¹⁶²

Previous strategies for prevention of influenza in the United States and other countries have focused on targeting vaccines to persons at higher risk for influenza-related complications (see Table 32-4) and on individuals in close contact with these high-risk individuals. Such recommendations were complex and in some ways difficult to implement, leading to lower than desired vaccine uptake. In addition, it was recognized that more universal vaccination strategies, particularly of children, might be able to impact the spread of influenza in the community. Currently, the United States and many other countries have adopted a universal vaccination strategy with annual vaccination of all members of the population. This, of course, includes health care providers, and most institutions have adopted a policy of mandatory vaccination of individuals in contact with patients.

Antibody responses to influenza A virus, whether induced by vaccination or natural infection, are predominantly directed at the "globular head" domain of the HA protein, which is involved in binding host cells. This domain of HA mutates frequently, and amino acid substitutions in this domain allow the new viral variant to escape recognition by antibodies that developed in response to the original virus. Thus, new antigenic variant viruses emerge regularly, and this necessitates development and administration of new influenza vaccines each year. The costly and logistically complex requirement for a distinct influenza vaccine each year has stimulated efforts to develop a vaccine that targets conserved domains of the influenza virus hemagglutinin, rather than the variable globular head domain. Although these efforts have revealed evidence for broadly neutralizing antibodies produced by certain subjects, a clear strategy for production of a vaccine that induces broadly neutralizing antibodies has not yet emerged.¹⁶³⁻¹⁶⁵

Antivirals. Two classes of antiviral agents are currently available for the treatment and prevention of influenza: the *M2 inhibitors* (M2Is) amantadine and rimantadine (adamantanes) and the *neuraminidase inhibitors* (NAIs) oseltamivir and zanamivir. The M2 protein is located in the viral envelope, where it functions as a proton channel and is essential for viral escape into the host cell cytoplasm, where viral replication takes place. The M2-inhibiting adamantanes specifically block the ion channel function of the influenza A M2 protein and are not active against influenza

B viruses. Resistance to these drugs emerges readily in treated individuals, particularly children,¹⁶⁶ and there may be prolonged shedding of resistant viruses in immunocompromised patients even after therapy is terminated.¹⁶⁷ For reasons that remain unclear, the first decade of this century has seen the emergence and spread of adamantane-resistant influenza A (H3N2) viruses,¹⁶⁸ and pH1N1 viruses are also uniformly resistant. Therefore, the adamantane M2I drugs do not have utility against current influenza viruses but might be used if susceptible strains emerge in the future.

NAIs are potent inhibitors of influenza virus in vitro and in vivo because neuraminidase activity is essential for viral release, a necessary step for viral spread to other cells. Influenza B viruses are somewhat less sensitive than influenza A viruses but are well within clinically achievable concentrations. Avian viruses with all nine known neuraminidase subtypes are also sensitive. Although zanamivir and oseltamivir have an identical mechanism of action and similar profile of antiviral activity, they have differing pharmacologic properties. Zanamivir is not orally bioavailable and is administered as a dry powder for oral inhalation, using the so-called “diskhaler” device. Oseltamivir phosphate is an orally bioavailable ethyl ester prodrug that is rapidly absorbed from the GI tract and converted in the liver by hepatic esterases to the active metabolite, oseltamivir carboxylate. The metabolite is excreted unchanged in the urine by tubular secretion, with a serum half-life of 6 to 10 hours.

The major adverse effects reported for oseltamivir have been GI upset in about 10% to 15% of recipients, probably due to irritation caused by rapid release of the drug in the stomach. Rates of nausea can be substantially reduced if the drug is taken with food. Adverse effects reported for zanamivir have been at essentially the same rate as in placebo recipients. However, postmarketing surveillance has found that inhaled zanamivir may be uncommonly associated with bronchospasm in influenza patients, particularly those with underlying airways disease; this acute bronchospasm has sometimes been severe or fatal.

The dose of oseltamivir should be reduced to 75 mg once daily in individuals with renal impairment (i.e., with creatinine clearance 15–30 mL/min and 75 mg every other day in prophylactic treatment). No data are available regarding the use of the drug in individuals with more significant levels of renal impairment. Likewise, no information is available regarding the use of oseltamivir in individuals with hepatic impairment. Clinically significant drug interactions have not been reported. Because the drug is eliminated by tubular secretion, probenecid increases serum levels of the active metabolite approximately twofold. However, dosage adjustments are not necessary in individuals taking probenecid. Coadministration of cimetidine, amoxicillin, or acetaminophen has no effect on serum levels of oseltamivir or oseltamivir carboxylate.¹⁶⁹ Because zanamivir has no significant systemic absorption, there are no recommended dosage reductions.

Both NAIs are effective in the treatment of influenza due to either influenza A or B virus if administered within the first 48 hours of symptom onset, with reduced duration of illness and earlier return to work or normal activities. Meta-analysis of results of these trials has also suggested that early treatment may reduce the frequency of influenza-

related complications, with reductions in the use of antibacterials and in hospitalization.¹⁷⁰ Only oseltamivir is currently licensed for use in children younger than 5 years of age. Administration of oseltamivir liquid at a dose of 3 mg/kg in children 0 to 8 months of age, and 3.5 mg/kg in children 9 to 11 months of age, twice daily for 5 days reached target ranges. Earlier studies showed that they were well tolerated and resulted in a 36-hour reduction in the duration of symptoms in children with influenza A.^{170a,171} NAIs have also been used successfully for seasonal or contact prophylaxis.

Initial placebo-controlled trials of NAI therapy conducted primarily in otherwise healthy adults did not capture substantial numbers of influenza complications. However, pooled analyses of these studies of early therapy with zanamivir¹⁷² and oseltamivir^{170,173} demonstrated a significant reduction in the rate of influenza complications in treated individuals. Subsequent experience in the emerging epidemic of pH1N1 virus has also suggested a beneficial effect of early therapy on complications. These include observations in hospitalized patients^{174,175} and surveillance data suggesting that therapy as late as 5 days improved survival of hospitalized patients.¹⁷⁶ Surveillance data have also suggested that treated children had lower rates of complications.¹⁷⁷

Mutations within the catalytic framework of the NA that abolish binding of the drugs have been described.^{178,179} Depending on the location of the mutation, these viruses may be specifically resistant to only one of the inhibitors.¹⁸⁰ Resistance mutations in the NA may also be associated with altered characteristics of the enzyme with significantly reduced activity.^{181,182} Drug-resistant viruses are most commonly isolated from treated children.¹⁸³ Viral fitness appears to be less compromised by oseltamivir resistance mutations in the N1 neuraminidase,¹⁸⁴ and resistance was common among seasonal H1N1 viruses before the pH1N1 pandemic. Currently, the majority of seasonal influenza viruses are susceptible to both drugs, but N1 resistance is being sporadically reported and it is important to continue to monitor susceptibility patterns.

Although the benefits of antiviral therapy were initially demonstrated as a shortening of illness duration in healthy adults with uncomplicated influenza, this is generally not considered the priority target group for antiviral therapy. Current recommendations include the use of antivirals in individuals at risk for more severe influenza, or in individuals with severe disease or requiring hospitalization.¹⁴⁹ Treatment should be started as early as possible, but even delayed therapy can be of benefit in hospitalized patients.

Treatment of patients requiring mechanical ventilation can be challenging. Administration of oseltamivir by nasogastric tube is effective, and intravenous preparations of zanamivir and the experimental NAI peramivir are available under compassionate use protocols.

MEASLES VIRUS

Measles virus is classified in the *Morbillivirus* genus of the Paramyxoviridae family and is structurally similar to parainfluenza virus and RSV. Its surface glycoproteins include a hemagglutinin responsible for attachment to cells, a *fusion* (F) protein responsible for cell membrane fusion and virus

penetration of cells, but no neuraminidase. The cell surface molecule SLAM (*Signaling Lymphocyte Activation Molecule*) serves as a receptor for entry of the virus into susceptible cells.¹⁸⁵ In addition, the complement regulatory protein CD46 can also serve as a receptor, particularly for the vaccine strain.¹⁸⁶ Only one serotype of wild measles virus is recognized, although minor antigenic differences are detectable by monoclonal antibodies. The human is the sole natural host for measles virus.

Epidemiology and Transmission

Measles is found worldwide, but epidemic patterns vary depending on population density and levels of acquired immunity. Before vaccine use, measles arose in epidemics of 3 to 4 months in duration every 2 to 5 years in temperate regions.¹⁸⁷ Except in isolated areas, most people experienced infection by 20 years of age, and 90% of reported cases were seen in those younger than 10. Infection confers life-long protection against measles, although asymptomatic reinfections may develop.

Measles virus infection is highly contagious and can spread despite high levels of acquired immunity in the population. Airborne transmission via small-particle aerosols and possible spread by fomites appear to account for its high communicability. The virus remains infectious in small-particle aerosols for several hours at low relative humidity and has caused secondary infections in the absence of face-to-face contact with an index case.¹⁸⁸ The incubation period is usually 9 to 14 days but may be longer in adults. Patients are most infectious during the late prodrome, when respiratory involvement contributes to creation of infectious aerosols. The virus may be shed for several days after the onset of rash in normal hosts.

Measles-associated mortality in developed countries is usually 0.1% or less but approaches 2% of cases in the developing world. Case fatality rates have been as high as 25% in some areas. Most deaths result from respiratory tract involvement, neurologic complications, or both, and are related to various combinations of malnutrition, young age, and complications of the immunosuppression induced by measles virus infection itself.

Pathogenesis

The respiratory tract and possibly the conjunctival epithelium are the portals of entry and initial sites of replication of measles virus, as well as subsequent target organs of disease expression. An initial viremic phase leads to infection of mononuclear phagocytes including dendritic cells, and a second phase of viremia, corresponding to the prodromal stage of illness, results in dissemination of virus to the epithelial cells of the skin, respiratory tract, gut, bile duct, and bladder and to lymphoid organs.

Measles virus-induced giant cells may be present in the tonsils, appendix, other lymphoid organs, and various epithelial surfaces, including those of the respiratory tract. The effects of infection on the lymphoid system include leukopenia and immune suppression manifested by cutaneous anergy and depressed natural killer cell activity¹⁸⁹ for weeks after rash onset. The mechanisms by which measles induces immunosuppression are incompletely understood, but infection of dendritic cells and suppression of IL-12 production are thought to play an important role.¹⁹⁰

The onset of the rash correlates temporally with the development of host immune responses and subsequent termination of virus shedding. Skin rash develops in agammaglobulinemic patients with measles, whereas progressive giant cell (measles virus) pneumonia without rash may develop in those with deficient cell-mediated immune function. The pathologic changes in involved organs include lymphoid hyperplasia, mononuclear cell infiltration, and the presence of multinucleated giant cells. Lower respiratory tract involvement may be associated with the destruction of ciliated respiratory epithelium, interstitial pneumonia, epithelial cell hyperplasia, and syncytial cell formation.

Clinical Illness

Typical Measles. The typical prodrome of measles lasts 2 to 8 days and is characterized by fever, malaise, anorexia, cough, coryza, and conjunctivitis. Koplik spots, which are erythematous macular lesions with central white-yellow or gray puncta, appear on the buccal or labial mucous membranes toward the end of the prodromal period. The maculopapular, erythematous eruption begins about the face and neck and progresses to involve the upper body, trunk, and extremities. The rash typically resolves after 5 to 6 days in the order in which it appeared. The fever abates and symptoms improve several days after the appearance of the rash, although persistent cough is common. Leukopenia is common during the prodromal and early exanthematous stages of measles. Pronounced leukopenia (<2000 cells/ μ L) is associated with a poor prognosis. The development of neutrophilic leukocytosis suggests the possibility of bacterial superinfection or other complications.

Lower respiratory tract complications develop in 4% to 50% of patients. These include bronchitis, pneumonia, and, less often, croup or bronchiolitis. In young adults, a multilobar reticulonodular opacity is the most common radiographic abnormality (see eFig. 32-4).¹⁹¹ In the absence of bacterial superinfection or atypical measles, pleural effusion or lobar consolidation is uncommon. In patients with altered cell-mediated immune function, and rarely in apparently normal persons, infection by wild measles virus can cause a lethal giant cell pneumonia with or without rash.¹⁹² Severe virus-induced pneumonia has been recognized during measles in pregnant women¹⁹³ and in those infected with HIV.¹⁹⁴ In hospitalized patients, mortality rates are approximately 70% in oncology patients and 40% in HIV-infected patients.¹⁹²

Secondary bacterial infection has been found in 30% to 50% of young adults with measles-related pneumonia. Symptoms and signs indicative of bacterial infection usually begin 5 to 10 days after onset of the rash. One study employing transtracheal aspiration found a range of bacterial pathogens in adults, most commonly *Haemophilus influenzae*, *Neisseria meningitidis*, and *S. pneumoniae*.¹⁹¹ Up to 30% of cases are complicated by otitis media or sinusitis. Acute nonrespiratory complications include hepatitis, encephalitis, keratitis, mesenteric adenitis, as well as a high rate of severe diarrheal disease in children in developed countries. Measles infection or vaccination may be accompanied by conversion of the tuberculin skin reaction from positive to negative for weeks. Measles may exacerbate active

tuberculosis, but whether measles reactivates dormant tuberculosis is unresolved.¹⁹⁵

Atypical Measles. An unusual clinical syndrome has been recognized in adolescents and young adults who received the inactivated measles vaccine between 1963 and 1968 and who were subsequently re-exposed to the wild virus. The illness begins abruptly, with high fever, headache, myalgia, vomiting, abdominal pain, and nonproductive cough. Respiratory symptoms, including dyspnea, coryza, sore throat, and pleuritic chest pain, are common. A polymorphous eruption, which may include vesicles, petechiae, purpura, and urticarial lesions, begins typically on the distal extremities and spreads proximally over 3 to 5 days. Although Koplik spots are absent, conjunctivitis and glossitis with strawberry tongue have been described.

Pulmonary abnormalities are found in most cases, and acute respiratory failure has been described. Chest radiographic changes include patchy, diffuse, or dense lobar opacities, pleural effusions, and hilar lymphadenopathy.¹⁹⁶ Residual nodular pulmonary opacities may persist for years and lead to diagnostic confusion. The fever and other symptoms usually resolve in 1 to 3 weeks. The pulmonary function changes in atypical measles include transient hypoxemia and significantly reduced lung volumes.

Diagnosis

The diagnosis of measles is most readily confirmed in immunocompetent patients by detecting measles virus-specific IgM by ELISA. In immunodeficient patients, detection of measles virus by nucleic acid amplification of urine or of samples obtained by throat or nasopharyngeal swab is sensitive and specific; samples can be sent to the U.S. Centers for Disease Control (<http://www.cdc.gov/measles/lab-tools/rt-pcr.html>). Measles virus may also be isolated from the blood, urine, or respiratory secretions during the prodrome and up to several days after the exanthem appears. Isolation of virus from clinical specimens has been performed in several types of human and monkey cell cultures but is slow and inefficient. Respiratory and conjunctival secretions or urine sediment stained by various techniques reveals multinucleated giant cells in most cases. Immunofluorescent staining of skin biopsy specimens, cells from combined nasopharyngeal and throat swab samples, and, less often, exfoliated cells in the urine demonstrates measles virus antigens early in the disease.

Treatment and Prevention

The treatment of measles involves supportive care and specific therapy for bacterial complications. No antiviral agents have proven clinical value, but aerosol and intravenous ribavirin and immunoglobulin have been used in treating measles pneumonia.^{193,197} Vitamin A therapy reduces morbidity and mortality in severe measles in children.¹⁹⁸ Patients suspected of having measles should be placed in respiratory isolation.

The live attenuated measles vaccine currently used in the United States provides durable immunity in more than 90% of recipients. Recent outbreaks have seen cases in adolescent and adult recipients of two doses of measles vaccine, but the illness has been mild and not associated with trans-

mission.^{199,200} The vaccine is safe, and it has been conclusively shown to have no association with autism.^{201,202} There have been recent outbreaks of measles in undervaccinated communities in the United States, often introduced by an imported case in an immigrant or traveler.^{202a}

METAPNEUMOVIRUSES

The *human metapneumoviruses* (hMPVs) are pleomorphic particles with short envelope projections, resembling other paramyxoviruses.²⁰³ These viruses are closely related to the pneumoviruses (of which RSV is the human example), differing only by the absence of two nonstructural proteins and a slightly different arrangement of gene order on the negative-sense, single-stranded RNA genome. The basic virology of these viruses closely resembles that of RSV. Envelope glycoproteins include the SH (*sulfhydryl*), F (*fusion*), and G (*attachment*), although there is little sequence homology in these genes between RSV and hMPV.²⁰⁴ By analogy, it is expected that antibody to the F and G proteins of hMPV would play a role in protection against reinfection. At least two major genetic groups have been identified, roughly corresponding to subgroups A and B of RSV.²⁰⁵ Sequential infections of the same individual tend to involve different genogroups. The role of cell-mediated immunity in this infection is largely unexplored.

Epidemiology and Transmission

hMPV infections are distributed worldwide and have been documented in both the outpatient²⁰⁶ and inpatient setting.²⁰⁷ Recent estimates of disease burden based on PCR diagnostics suggest that hMPV results in 1 to 1.2 hospitalizations, 13 emergency department visits, and 55 outpatient visits per 1000 children younger than 5.^{208,209} Children younger than 6 months are at the highest risk. As with many other respiratory viruses, infection is linked to day care attendance.²¹⁰ Serologic studies suggest that essentially all children have been infected by age 5.²⁰³

Similar to the case with RSV, disease has also been documented in adults and in the elderly,²¹¹ although asymptomatic infection is also common in adults. Outbreaks of severe disease have been documented in residential care facilities in older adults.^{212,213} Severe disease may also be seen in immunocompromised subjects such as hematopoietic stem cell transplant recipients (see eFig. 91-6).^{214,215} The mode of transmission has not been documented but is likely to be via droplet spread as with RSV. There is a clear seasonal variation in incidence, with the majority of cases appearing during the winter months.²⁰⁶

An interesting feature of the epidemiology of these viruses is that children with hMPV are often coinfecting with other respiratory viral pathogens, especially RSV.²¹⁶ Dual infections with both viruses may result in more intense bronchiolitis in some infants.²¹⁷ hMPV was also detected in many cases of SARS but did not appear to exacerbate this illness.²¹⁸

Clinical Features

Human metapneumoviruses appear to be responsible for a spectrum of acute respiratory illnesses ranging from mild or asymptomatic infection to severe bronchiolitis and pneumonia. The clinical picture most closely resembles that

of RSV, and bronchiolitis is the major manifestation in children.^{206,219} Clinical features in hospitalized children include wheezing and hypoxia.²²⁰ A variety of other lower and upper respiratory tract syndromes are also associated with hMPV infection, including croup and pneumonitis.^{206,207} There are no clinical features that can distinguish between disease caused by hMPV and RSV, although RSV may be more severe.

Symptomatic infection in adults and in the elderly has also been described.²¹¹ hMPV infections of young adults had features of the common cold, with nasal congestion, rhinorrhea, cough, and hoarseness predominating. Frail elderly and high-risk adults had lower rates of hMPV infection but more severe clinical symptoms, with significantly higher frequencies of dyspnea and wheezing, and more prolonged illness.²¹¹ Elderly patients with hMPV infection were hospitalized with diagnoses of COPD, bronchitis, and pneumonia. hMPV appears to be a leading cause of respiratory tract infection in lung transplantation patients.²²¹ In one study, hMPV was the most commonly detected RNA virus in BAL samples from immunocompromised patients.²²²

Pathogenesis

Relatively little is known regarding the pathogenesis of this disease. In hospitalized children with hMPV, levels of nasal secretion RANTES have been reported to be suppressed, while levels of nasal IL-8 were increased.²²³ The immune responses elicited by hMPV are similar to those of RSV but often not as vigorous.²²⁴

Diagnosis

Viral culture is slow and has low sensitivity. Most infections have been detected by nucleic acid amplification techniques, which are available in panels to detect and identify respiratory viruses^{224a-d} (see Chapter 17).

Prevention and Treatment

Treatment is supportive. No antiviral agents or vaccines are currently licensed for treatment or prevention of hMPV infections, and this is unlikely to change in the near future. Ribavirin is as active in vitro against hMPV as it is against hRSV,²²⁵ but there are no data to support the therapeutic efficacy of this drug. There are no specific monoclonal antibodies available for clinical use, although intravenous immunoglobulin has been suggested as a possible therapeutic agent in immunocompromised hosts.²²⁶

PARAINFLUENZA VIRUSES

Parainfluenza viruses belong to the *Paramyxovirus* genus of the Paramyxoviridae family, which includes mumps virus and important veterinary pathogens. This group of medium-sized (150 to 200 nm), pleomorphic, enveloped viruses has a nonsegmented, single-stranded RNA genome contained in a helical nucleocapsid. The human parainfluenza viruses are separated into types 1 to 4, and type 4 is further divided into subtypes A and B, on the basis of antigenic differences. One envelope glycoprotein (HN) has both hemagglutinin and neuraminidase activity and mediates adsorption of virus to host cell receptors for entry into host cells, as well as subsequent release of new virions from

infected cells after viral replication. The F glycoprotein has membrane-fusing activity and is responsible for viral penetration into cells and for the formation of multinucleated syncytial cells. Antibodies against the HN and F are involved in protective immunity.

Epidemiology and Transmission

Parainfluenza viruses have a worldwide distribution, and almost all persons are infected initially during childhood. Parainfluenza type 3 virus may cause infection in infancy, whereas infections by type 1 and 2 viruses appear to be prevented by maternal antibody and usually arise later. National surveillance has demonstrated distinct seasonality for type 1 viruses, with biennial outbreaks in the fall of odd-numbered years. In contrast, yearly outbreaks of type 3 virus take place in the spring, with smaller autumn outbreaks in those years without type 1 outbreaks. Type 2 viruses are detected much less frequently but appear to be more prevalent in the autumn; type 4 does not exhibit notable seasonality.²²⁷

Parainfluenza viruses appear to be transmitted from person to person by direct contact with infectious respiratory secretions or by large-particle aerosols. The incubation period is approximately 3 to 6 days. Virus is transmitted readily in families. Outbreaks of infection have been seen in closed populations, such as nurseries, day care centers, and hospitals, in which susceptible populations have high attack rates (40% to 80%).

Parainfluenza virus infections, most commonly type 1 virus, are associated with approximately 40% of croup cases and up to 75% of those with a documented viral cause, with smaller proportions of pneumonia or bronchiolitis cases in children. The incidence of croup and lower respiratory tract disease due to type 1 or 2 infections is highest between 6 months and 3 years of age, whereas parainfluenza type 3 is an important cause of bronchiolitis or pneumonia in infants younger than 6 months. Reinfections with parainfluenza viruses are common and, in young children, may arise within several months of each other. Recent population-based disease burden estimates suggest that 1 in 1000 children younger than 5 experience parainfluenza virus-related hospitalization, and that about 6.8% of hospitalizations for fever or respiratory illness in this age group can be attributed to parainfluenza virus.²²⁸

Pathogenesis

Although viremia has been described, replication of the virus is generally restricted to the respiratory tract mucosa. The quantity of virus shed in respiratory secretions tends to parallel the severity of illness.²²⁹ Virus shedding commonly continues for periods of 8 to 10 days in initial infections but may last for 3 weeks or longer. Prolonged shedding (months) of parainfluenza virus type 1 or 3 has been reported in apparently normal hosts,²³⁰ as well as in immunodeficient children.²³¹

The pathologic findings in fatal cases are typical of other viral pneumonias and include peribronchiolar and alveolar lymphocytic infiltration.²³² Infection of the tracheal epithelium with localized edema and fibrinous exudate contributes to airway narrowing in croup. The mechanisms that account for the laryngotracheal localization of parainfluenza virus-induced disease are unresolved. Virus-host cell

interactions (specifically cleavage of the F protein) and other host factors, including the nature of the immune response, are postulated to play contributory roles in the pathogenesis of croup. The nasopharyngeal secretion concentrations of parainfluenza virus–specific IgE and of histamine and leukotriene C4, as well as cellular responses to viral antigen, are higher in patients with wheezing than in those with upper respiratory tract illness alone.²³³

Clinical Illness

Primary infections are usually symptomatic and are associated with the most severe forms of illness. Initial infections with parainfluenza virus types 1 to 3 cause febrile rhinitis, pharyngitis, laryngitis, and bronchitis in children. Depending on the serotype causing infection, 50% to 80% of primary infections are associated with fever, and up to one third of children have evidence of lower respiratory tract involvement. In parainfluenza virus type 1 and 2 infections, lower respiratory disease is principally manifested as croup, whereas type 3 infection has been associated with croup, bronchiolitis, and pneumonia.

In adults and older children, reinfections are frequently asymptomatic. Symptomatic infections are manifested as common colds, usually without fever, and less often pharyngitis, tracheobronchitis, or influenza-like illness. Pneumonia and exacerbations of chronic airway disease have been described following parainfluenza virus infection in adults and in the elderly.²³⁴

Although uncommon, parainfluenza viruses can cause serious lower respiratory tract disease, including fatal pneumonia with or without giant cells, in children with immunodeficiency or leukemia, and in pediatric and adult stem cell transplant recipients.²³⁵ Nosocomial outbreaks in immunosuppressed patients have been reported.²³⁶ Because upper respiratory illness may be absent and nasopharyngeal cultures negative, BAL is often required for diagnosis.

Diagnosis

Rapid diagnosis of parainfluenza infection can be made by detection of viral antigen or RNA in respiratory secretions obtained using throat or nasopharyngeal swabs. Detection of parainfluenza RNA is performed in multiplex nucleic acid amplification panels for respiratory viruses^{224a-d} (see Chapter 17), which may be more readily available than rapid antigen detection assays. Respiratory secretions contain the virus at the time of symptom onset. Viral culture is also sensitive, and parainfluenza viruses can be isolated as early as 3 days and usually within 10 days after inoculation of cell culture with specimens from infants and children. Virus replication in cell culture is usually detected by hemadsorption of guinea pig erythrocytes or immunofluorescence.

Treatment and Prevention

There are currently no available antiviral agents of proven effectiveness against parainfluenza virus. Ribavirin is active against parainfluenza viruses in vitro and would theoretically be expected to be active in vivo as well. Anecdotal reports in immunodeficient children with severe parainfluenza virus infections suggest that aerosolized ribavirin may be associated with antiviral effects and clinical benefit,²³⁷ although delayed treatment with aerosol ribavirin was

not associated with improved survival in bone marrow transplant recipients.²³⁸ The combination of aerosolized ribavirin and intravenous immunoglobulin is frequently used in immunocompromised patients,²³⁹ but there is no direct evidence of efficacy. The sialidase DAS-181 is active in vitro and in small clinical studies^{240,240a} but is not currently available for clinical use.

Initial attempts to develop vaccines for the prevention of parainfluenza viruses involved use of formalin-inactivated virus. However, these vaccines failed to provide protection in field trials carried out in the 1960s, despite being modestly immunogenic. In contrast to RSV vaccines, the use of formalin-inactivated parainfluenza vaccine was not associated with enhanced disease on subsequent infection. Several approaches have been explored subsequently, including use of live attenuated viruses and recombinant subunit vaccines. Clinical trials of these are ongoing.

RESPIRATORY SYNCYTIAL VIRUS

RSV is classified in the *Pneumovirus* genus of the Paramyxoviridae family. Similar in structure to parainfluenza viruses, RSV is a pleomorphic (150 to 300 nm), enveloped virus with a single-stranded, nonsegmented RNA genome. The surface proteins include the F protein responsible for fusion of the viral envelope with the host cell membranes and formation of syncytium, and the G protein, a heavily glycosylated protein responsible for attachment to cells. Antibodies against the F and G protein neutralize RSV in vitro, but antibodies against the G do not prevent syncytium formation. Two major antigenic groups (designated A and B)²⁴¹ are distinguished primarily by differences in the G glycoprotein. The clinical and epidemiologic importance of strain variation are under study, but infections by group A strains appear to be more severe.²⁴² Further antigenic subgroups and genomic heterogeneity are recognized among circulating RSV strains.

Epidemiology and Transmission

RSV is worldwide in distribution and, in temperate climates, causes annual outbreaks of infection in the late fall, winter, or spring. Epidemics are associated with increases in pediatric hospitalizations and deaths due to lower respiratory tract illness in infants and young children.²⁴³ Nearly 50% of children are infected within the first year of life, and almost all have been infected by 3 years of age. Reinfections in children and adults are quite common even with the same strain,²⁴⁴ suggesting immunity is only partial. Epidemiologic factors related to serious illness in infected infants include low socioeconomic status, crowding, maternal smoking, lack of breast feeding, day care center attendance, and history of allergic disease. RSV is also recognized as a cause of severe disease in older adults²⁴⁵ and may result in a greater total burden of mortality in the elderly than in infants.¹²⁵

RSV spreads by large-particle aerosols during close personal contact and by hand contamination with infectious secretions and subsequent self-inoculation of the eye or nose. RSV is a major nosocomial pathogen on pediatric wards, and there can be high attack rates during outbreaks in hospitals, transplantation units, day care centers, and geriatric homes. Attack rates in children have approached

100% during outbreaks in day care centers and are commonly 20% to 50% in hospital staff and patients during epidemic periods. In the family setting, secondary infection develops in approximately one half of infants and up to one third of adult contacts after introduction of virus by an older sibling.²⁴⁶

Pathogenesis

Viral replication generally begins in the upper respiratory tract with gradual (4- to 5-day) progression to involve the lower respiratory tract. In children with normal immunity, the duration of viral shedding ranges from 1 to 3 weeks. Clinical signs of bronchiolitis include airway trapping and wheezing. Pathologic findings in RSV bronchiolitis include necrosis of bronchiolar epithelium, loss of ciliated epithelial cells, and marked peribronchiolar mononuclear inflammation.²⁴⁷ Virus-induced cytopathology and associated submucosal edema lead to obstruction of smaller bronchioles, particularly in infants, with distal collapse or air trapping.

Both serum and mucosal antibody responses are seen but are associated with limited protection. The magnitude of the antibody response is related to the age at primary infection, with infants younger than 8 months having approximately 10-fold lower antibody levels than older ones.²⁴⁸ Reinfection may take place within weeks after primary infection.²⁴⁴ Circulating and mucosal antibody levels increase with each successive infection and appear to be associated with milder illness. High titers of serum neutralizing antibody are generally associated with a lower risk of severe illness in infants and children.²⁴⁹

Cell-mediated immunity appears to be important in viral clearance and may also be involved in pathogenesis. For example, adult bone marrow transplant patients are at high risk of severe lower respiratory disease from RSV which is likely due to prolonged periods of decreased cellular immunity.^{250,251} In contrast, AIDS patients with decreased cellular immunity may suffer only mild disease, but viral shedding can continue for up to 6 months.²⁵²

Studies investigating the association of severe RSV disease in infants with genetic polymorphisms have implicated several candidate innate and adaptive immune genes including surfactants, TLR4, and several cytokine and chemokine genes as modulating the severity of RSV disease.

Clinical Illness

The clinical manifestations of infection depend on both the age and immunologic state of the host. In infants and young children, upper respiratory illness accompanied by fever and otitis media is common. RSV is the major cause of lower respiratory tract illness in infants and young children and accounts for 45% to 90% of bronchiolitis, up to 40% of pneumonia, and smaller proportions of croup and bronchitis cases in this age group. Most severe infections are seen in infants younger than 6 months, and almost all primary infections are symptomatic, with 40% or more associated with bronchiolitis or pneumonia. Approximately 1% to 2% of infections result in hospitalization, and about one in ten hospitalized infants require mechanical ventilatory support.

The risk of hospitalization and severe bronchiolitis is particularly high in infants with congenital heart disease, chronic lung disease, or immunodeficiency. In addition,

infants born prematurely are also at risk for severe disease, perhaps because they lack maternal antibody. Mortality is usually 0.5% to 1.5% in previously healthy infants hospitalized with RSV disease but is 15% to 40% in those with primary immunodeficiency, cancer chemotherapy, or pulmonary and heart disease. Pulmonary hypertension is associated with a particularly high frequency of poor outcomes. Severe disease has also been associated in children with a family history of asthma and those exposed to cigarette smoke in the household.²⁵³ However, it is important to recognize that the majority of those hospitalized with RSV are previously healthy young children.²⁴³

Chest radiographic findings in lower respiratory tract disease include bronchial wall thickening, peribronchial shadowing, air-trapping (eFig. 32-12A), and, in pneumonia, multilobar patchy shadowing or poorly defined nodularity (Fig. 32-3, eFig. 32-12B). Although no radiographic pattern is specific, air trapping, alone or with other abnormalities, is highly associated with RSV infection in hospitalized children.²⁵⁴ Chest CT findings (eFig. 32-13) are relatively nonspecific, often resembling other viral pulmonary infections, including multifocal areas of ground-glass opacity, consolidation, and small nodules, which may show branching configurations ("tree-in-bud" opacity).

The most common physiologic abnormality is hypoxemia that may persist for weeks after apparent recovery.²⁵⁵ Prolonged pulmonary function abnormalities, including increased airway resistance, peripheral airway obstruction, and decreased arterial oxygen saturation, have been detected in children years after bouts of bronchiolitis.²⁵⁶ Bronchiolitis in infancy has also been associated with an increased risk of subsequent recurrent wheezing and cough and airway hyperreactivity.

In adults, one half or more of recurrent infections are associated with upper respiratory tract illness. Adults typically experience coryza, pharyngitis, and cough, sometimes accompanied by low-grade fever. Bronchitis, influenza-like illness, pneumonia, and exacerbations of asthma and chronic bronchitis have also been described in adults with RSV infection. In the United States, approximately 170,000 hospitalizations and more than 10,000 deaths are associated with RSV annually in adults older than 65.¹²⁵ In elderly adults, the clinical features of RSV infection can mimic those of influenza, although fever is less frequent and wheezing is more frequent.²⁵⁷ In one study, RSV infection was seen in 3% to 7% of healthy elderly and 4% to 10% of high-risk adults annually. Compared with influenza, ICU admissions were higher, and mortality was similar, at 7% to 8%.²⁴⁵ RSV also contributes to 5% to 10% of COPD exacerbations.²⁵⁸ Older patients with severe RSV infection had a longer period of viral shedding, higher levels of mucosal IL-6, and a higher frequency of circulating activated T cells compared with young patients with mild disease,²⁵⁹ suggesting viral loads and inflammation may play a role in disease severity.

In immunosuppressed children and adults, RSV, often nosocomially acquired, causes severe lower respiratory tract disease. Upper respiratory tract illness usually precedes the development of pneumonia, and complicating sinusitis and otitis media are common. Two thirds or more of the bone marrow transplant recipients that develop RSV pneumonia will die of the infection.

Diagnosis

The most rapidly and readily available approach to establishing RSV infection is by rapid antigen detection. The sensitivity of such techniques is dependent on the quality of the nasopharyngeal specimen, with nasopharyngeal aspirates superior to brushings or swabs.²⁶⁰ In addition, sensitivity is related to the amount of antigen being shed, so it is generally greater in children than adults. In transplant patients with suspected RSV pneumonia, samples of the lower respiratory tract by BAL are more sensitive than throat swabs for detection of RSV antigens.²⁶¹ PCR-based respiratory viral multiplex assays for detection of RSV and other respiratory viruses have also been approved by the U.S. Food and Drug Administration and are becoming widely available^{224a-d} (see Chapter 17). RSV grows well in several human cell lines, in which it causes formation of characteristic syncytia. Virus can be detected as early as 2 days and usually within 7 days on primary isolation from specimens collected from children.

Treatment and Prevention

Correction of hypoxemia is the most important aspect of managing RSV lower respiratory tract disease. Ribavirin is highly active against RSV in vitro, and aerosolized ribavirin has been shown to reduce viral shedding and shorten the course of illness in some but not all studies. Aerosolized ribavirin is currently recommended for use only in selected infants and young children who are at high risk for serious RSV disease.²⁶²

In immunosuppressed patients, particularly hematopoietic stem cell transplant recipients, both aerosolized ribavirin and high-dose oral ribavirin have been used for early treatment to prevent progression to pneumonia.²⁶³ Recent studies suggest that intermittent aerosolized ribavirin is as effective as continuous aerosolized ribavirin in these patients.²⁶⁴ Once RSV pneumonia has developed, intravenous ribavirin alone is ineffective but, if treatment is initiated before the onset of respiratory failure, combinations of aerosolized ribavirin with intravenous immunoglobulin, and particularly palivizumab (see later) may be beneficial.^{265,266} In adults, short courses of systemic corticosteroids for RSV-related wheezing did not affect viral loads or shedding and only mildly diminished antibody responses.²⁶⁷

An effective vaccine for prevention of RSV has not yet been developed. In a study of formalin-inactivated RSV vaccine conducted in the 1960s, vaccinated infants developed more severe disease compared with unvaccinated children.²⁶⁸ The mechanisms of this enhancement remain uncertain, although studies in those vaccine recipients and in rodent models have implicated low levels or low affinity of the antibodies induced by the formalin-inactivated vaccine, which permitted excessive cytolytic T-cell responses to develop and cause tissue damage. Low-affinity antibodies may also have contributed to immune complex formation and deposition, leading to local inflammation.^{269,270} Formalin-inactivated RSV also primes a T helper 2 response, with high levels of interleukin 4 and interleukin 5, which can promote inflammation of small airways.²⁷¹ Although this adverse experience has prompted extra caution, current RSV vaccine development efforts are ongoing and focus on live attenuated and recombinant subunit vaccines.

In contrast to the earlier vaccine experience, passive transfer of antibody to the RSV F protein has been shown to be a highly effective means to prevent RSV morbidity in high-risk children. The currently commercially available product, palivizumab, is a humanized monoclonal antibody to the F protein.²⁷² Administration of palivizumab to infants with prematurity or bronchopulmonary dysplasia resulted in a 55% reduction in RSV-related hospitalizations and a lower incidence of ICU admissions.²⁷³ In a second trial, administration of palivizumab to infants and children with hemodynamically significant congenital heart disease was well tolerated and resulted in a 45% decrease in RSV-associated hospitalizations.²⁷⁴

Prophylaxis with palivizumab should be considered for infants younger than 24 months with chronic lung disease severe enough to require medical therapy within 6 months of the anticipated start of the RSV season.²⁷⁵ Prophylaxis with palivizumab (and not RSV-IVIG) should be given to infants with hemodynamically significant congenital heart disease and infants born before 32 weeks of gestation. Prophylaxis for infants between 32 and 35 weeks of gestation depends on the presence of other RSV risk factors, such as exposure to tobacco smoke, attendance at day care, school-aged siblings in the household, and congenital airway abnormalities. Palivizumab has not been shown to be effective in the therapy of established RSV disease.

Recommendations for interruption of nosocomial transmission include handwashing, decontamination of surfaces and inanimate objects, and isolation of infected patients. Use of disposable eye-nose goggles by pediatric staff reduces the risk of nosocomial RSV infection in both staff and patients.²⁷⁶ Regular use of gowns, gloves, and possibly masks by hospital staff caring for infected children may also reduce the risk of nosocomial RSV spread. Protective isolation of high-risk infants or deferring their elective admission has been recommended during institutional outbreaks of RSV.

RHINOVIRUS

Rhinoviruses (RVs) are species in the *Enterovirus* genus in the Picornaviridae family. The RV virion is a nonenveloped particle 30 nm in diameter with four major structural proteins. The genome of RV consists of single-stranded RNA of approximately 2.5×10^6 daltons and codes for a 240 kD protein that is cleaved into the structural units of the virion. RV genomes have been found to have 45% to 62% homology with poliovirus genomes. Poliovirus and RV differ, however, in the construction of their protein shells: that of RV being loosely packed with a resultant sensitivity to inactivation at low pH and that of poliovirus being tightly packed, providing the virion with resistance to acid inactivation. The acid sensitivity of RV and its optimum growth at 32°C to 34°C are thought to account for its replication in the nasal passages (and possibly large airways) but not in the GI tract.

On the basis of sequence data, rhinovirus are grouped into three genogroups: A, B, and C.²⁷⁷ In addition, three of the four proteins in the RV shell (VP1, VP2, and VP3) react with neutralizing antibody, forming the basis on which more than 100 antigenic types have been numbered. The presence of neutralizing antibody in serum and nasal

Figure 32-10 View of one side of rhinovirus shell drawn to scale with attached antibody molecule. *Top*, The protein shell is built of 12 pentamers, one of which is shown (white). Each of the five wedge-shaped subunits of the pentamer (white) is called a "protomer." The antibody binding site (brown) bridges protomers of two adjacent pentamers. *Bottom*, Surface organization of the protomer. Three of the polypeptide chains (VP1, VP2, VP3) making up each protomer are exposed on the virus surface, while the smallest polypeptide (VP4) is buried at the bottom of the protomer. The host-cell receptor is thought to bind near the base of the cleft formed by antigenic plateaus forming VP1, VP2, and VP3. The blunt-nosed binding site of the antibody is too wide to fit into the base of the cleft. (Courtesy Dr. Roland Rueckert, University of Wisconsin.)

secretions correlates with protection from infection. X-ray diffraction studies of RV have disclosed the presence of a large depression on the surface of the virus shell at a junction between the plateaus of the three proteins (Fig. 32-10).²⁷⁸ This depression contains the recognition site for the host cell receptor, *intercellular adhesion molecule-1* (ICAM-1), which binds 91 of the 102 known rhinovirus serotypes.²⁷⁹ RV serotypes that do not bind to ICAM-1 are referred to as the *minor receptor group viruses* and appear to utilize the low-density lipoprotein receptor.²⁸⁰ Manipulation of these receptor proteins has been explored as a potential control measure for rhinovirus infection.

Epidemiology and Transmission

RVs are worldwide in distribution. In the United States, RV has been observed to cause 0.74 to 0.77 infections per person per year in adults. RV is believed to produce even higher infection rates in children, leading to acquisition of antibody to the different RV types throughout childhood and adolescence, with peak antibody prevalence in young adults. Immunity to RV is type specific and confers long-lived protection following infection, although there may be second infections with the same virus type. The different immunotypes circulate in a given population in an apparently random manner. In the United States, RV infections are most prevalent in the early fall and late spring.

The major reservoir for RV is school children, who transmit RV infection among their peers in the classroom and

introduce it into their homes, infecting other family members. Studies of experimental RV colds in volunteers have shown that RV is most efficiently spread by contaminated fingers accidentally depositing virus into the nose or eye. Experimental RV transmission has also been achieved by the airborne route, presumably by large-particle aerosol. The relative importance of these two routes of RV transmission under natural conditions has not been determined.

Pathogenesis

Approximately two thirds of both natural and experimental RV infections result in overt illness. The incubation period of RV colds is usually 2 days but may be up to a week. Symptoms begin within 1 day following experimental infection. Small doses of RV instilled into the nose or eye of susceptible volunteers regularly lead to infection, indicating that mucociliary clearance is not effective against the virus. During the period of illness, sloughed ciliated epithelial cells containing viral antigen are present in nasal secretions.²⁸¹

In general, the number of RV-infected cells in the nasopharynx appears to be limited,²⁸² and infection does not lead to detectable damage to the epithelium of the nasal passages. These results have suggested that virus-induced cellular injury is not the direct cause of symptoms in RV colds and that inflammatory mediators play an important role. Nasal secretions during the initial response to RV infection are predominantly the result of increased vascular permeability, as demonstrated by elevated levels of plasma proteins in nasal secretions.²⁸³ Glandular secretions (lactoferrin, lysozyme, and secretory IgA) predominate late in colds.²⁸³ In contrast to the situation in allergic rhinitis, histamine does not appear to play a role in the induction of symptoms in colds. Nasal secretion kinin levels correlate with symptoms in natural and experimental colds, and intranasal administration of bradykinin causes increased nasal vascular permeability, rhinitis, and sore throat.²⁸⁴ *Interleukin* (IL)-1, IL-6, and IL-8 concentrations also increase in experimental RV colds and correlate well with symptom severity.²⁸⁵ Enhanced synthesis of proinflammatory cytokines and cell adhesion molecules in the middle ear may also contribute to the pathogenesis of otitis media associated with colds.²⁸⁶ Polymorphisms in the IL-6 gene affect the symptomatic response to experimental RV challenge in adults.²⁸⁷

Clinical Illness

RV colds vary in severity from mild episodes characterized by 1 to 2 days of coryza or scratchy throat to full-blown illnesses with profuse and prolonged rhinorrhea, pharyngitis, and bronchitis. The profile of a typical RV cold, based on composite results from young adults with natural infection, is shown in Figure 32-1. The median length of illness is 1 week, with symptoms lasting up to 2 weeks in one quarter of cases. Peak symptoms are usually seen on the second and third days of illness. The characteristics of RV illness are not distinctive enough to permit their differentiation from colds due to other respiratory viruses. RV is among the respiratory viruses implicated in the development of acute sinusitis and represents about half of all viruses recovered from middle ear effusions in children with acute otitis media.²⁸⁸ Recently, a clinical presentation indistinguishable from that of influenza has also been reported in healthy adults.²⁸⁹

RV alone or in combination with bacteria has been recovered from aspirates obtained by direct puncture of the maxillary sinuses of patients with acute sinusitis.²⁹⁰ Mucosal thickening and/or sinus exudates have been observed in up to 77% of subjects with acute colds.²⁹¹ These abnormalities are transient, and in uncomplicated cases they resolve within 21 days. However, clinically manifest acute bacterial sinusitis is seen in a small (0.5% to 5%) proportion of individuals with naturally occurring colds. It is presumed that the RV infection impairs mucociliary clearance and other local defenses in the sinus cavity, allowing secondary bacterial invasion.

There is increasing evidence for an important role of rhinoviruses in lower respiratory tract disease in adults and children.²⁹² RV is the second most frequently recognized agent associated with pneumonia and bronchiolitis in infants and young children and commonly causes exacerbations of preexisting airways disease in those with COPD or cystic fibrosis.²⁹³ Colds are generally more severe in atopic individuals and rhinoviruses are major causes of asthma exacerbation.²⁹⁴ Children with a history of wheezing/asthma had significantly more RV-associated hospitalizations than those without a history.²⁹⁵

RV infections may also be associated with severe lower respiratory tract disease in transplant patients²⁹⁶ and in some cases can be associated with prolonged shedding.²⁹⁷ These viruses can also be detected in lower respiratory tract disease in individuals with hematologic malignancy, often in conjunction with other pathogens.²⁹⁸

Diagnosis

Rapid tests for detecting RV nucleic acid are available in respiratory virus panels (see Chapter 17); they generally do not distinguish rhinoviruses from other enteroviruses. RVs can be isolated in cell culture, usually within 2 to 7 days after inoculation. Virus is present in nasopharyngeal secretions in highest concentrations during the first and second days of illness but may be shed for as long as 3 weeks. When indicated, identification of the specific serotype of a rhinovirus isolate is made by neutralization test.

Treatment and Prevention

The only effective therapy for RV colds currently available is symptomatic treatment of individual complaints. Remedies recommended for such treatment are described in the section on common cold in this chapter. Although hand washing is undoubtedly important in preventing transmission, a recent study could show no benefit to routine hand disinfection in the prevention of RV colds.²⁹⁹ As mentioned earlier, the plethora of rhinovirus serotypes suggests that an effective vaccine will not be forthcoming in the foreseeable future. Advances in understanding of the structural and molecular biology of the rhinoviruses has led to development of a number of strategies for antiviral intervention, including receptor blockade and capsid-binding agents. However, none of these agents has reached approval for clinical use.

VARICELLA-ZOSTER VIRUS

Varicella-zoster virus (VZV) is an enveloped double-stranded DNA virus with a large genome ($\approx 125,000$ bp). Varicella is

a highly contagious, childhood disease that typically causes community outbreaks in late winter and early spring months in temperate regions. Varicella spreads rapidly to household contacts, with an attack rate of nearly 90% within 2 weeks. Consequently, most adults in temperate areas have experienced infection during childhood, but a high proportion of adults in semitropical and tropical areas remain susceptible to primary infection.³⁰⁰ Herpes zoster is nonseasonal and is seen in persons of all ages, although its incidence increases almost linearly after 30 years of age. About 10% to 20% of adults experience zoster, typically as a single episode after the fifth decade of life. Clinically apparent reinfections can be seen with VZV.

Although the virus has been infrequently recovered from respiratory secretions of varicella patients, epidemiologic evidence indicates that the virus is spread from person to person through airborne transmission. Cutaneous lesions may also be the source of infectious virus. Susceptible persons have been infected after contact with patients with varicella, or, less often, with herpes zoster. Before the implementation of vaccination, VZV was an important cause of nosocomial outbreaks on pediatric wards, with spread by small-particle aerosols.

Pathogenesis

The incubation period of varicella averages 2 weeks, and almost all cases of varicella develop within 11 to 20 days after exposure. The initial portal of infection is the respiratory tract, with viremic dissemination leading to the extensive cutaneous and mucous membrane lesions. Following infection, VZV establishes latency in the posterior dorsal root ganglia. Reactivation of virus replication and centrifugal spread along sensory nerves lead to the unique dermatomal distribution of shingles (zoster). In immunocompromised hosts with zoster, virus may disseminate to other sites.

Clinical Illness

Varicella. In children with normal immunity, varicella is usually not associated with significant systemic or respiratory manifestations. The exanthem typically begins around the scalp and head, with subsequent involvement of the trunk and extremities. Lesions progress through various stages (erythematous macules, vesicles, pustules, crusts), so an area will have lesions in different stages of evolution. In contrast, in smallpox, a disease with which varicella was often confused, lesions begin on the face and spread outwardly to the extremities, and adjacent lesions are at the same stage of development.

In children and susceptible adults who are immunocompromised, particularly those with defects in cell mediated immunity, including HIV infection,³⁰¹ varicella follows a more severe course. Continued lesion development, particularly involving the extremities; high fever; and visceral involvement with pneumonia, meningoencephalitis, and hepatitis are common. During pregnancy, severe pneumonia can develop in approximately 10% of varicella cases.

Viral pneumonia is the major complication of varicella in normal adults, in whom the frequency is estimated to be 25-fold higher than in children.³⁰² Smoking is a significant risk factor. Pneumonia associated with varicella is usually apparent 1 to 6 days after the onset of rash. Symptoms

Figure 32-11 Acute varicella pneumonia. Frontal chest radiograph shows multifocal, bilateral, poorly defined nodular opacities in a predominantly perihilar and lower lobe distribution. No pleural effusion is present. (Courtesy Michael Gotway, MD.)

include cough, dyspnea, pleuritic chest pain, and hemoptysis. Physical findings other than fever and tachypnea are often modest. The intensity of the rash does not necessarily correlate with the severity of pneumonia. The characteristic chest radiographic pattern is that of diffuse nodular (1 to 10 mm) opacities (Fig. 32-11, eFig. 32-14), which may resolve with miliary calcified nodules (eFig. 32-15).³⁰³ Hilar lymphadenopathy, pleural effusions, and peribronchial opacities are frequently present. Pulmonary infarction may complicate the clinical picture. Chest CT in patients with varicella pneumonia typically shows multifocal or diffuse, variably sized nodules (1 to 10 mm), which may be circumscribed or poorly defined (eFig. 32-16). Ground-glass opacity halos may be seen around some of the nodules. Pulmonary function studies have found normal expiratory flow values but decreased carbon monoxide diffusing capacity, which may persist for months. However, many individuals with radiographic changes are relatively asymptomatic.

Herpes Zoster. Zoster represents reactivation of latent virus along one to three dermatomes and, in adults, is usually associated with pain. The thoracic dermatomes are involved in about one half of cases. Prolonged severe pain, or postherpetic neuralgia, can be a serious complication, with increased frequency in those older than 50.

Zoster presents more often in those receiving immunosuppressive therapy or chemotherapy for malignancies and at anatomic sites irradiated for treatment of malignancies. Depending on the degree of immunosuppression, herpes zoster may develop in 30% or more of patients. Cutaneous dissemination (defined as more than 20 lesions outside the primary dermatome) develops in 25% to 50% of immunosuppressed patients and in up to 2% of apparently normal patients with zoster. It is associated with visceral involvement including pneumonitis, as well as hepatitis, meningoencephalitis, and uveitis in approximately one half of those

affected. Mortality depends on the degree of immunosuppression and ranges from zero to 10%.

Diagnosis

A rapid diagnosis of herpes group infection can be established by cytologic examination of lesion scrapings (Tzanck smear and others), which has a sensitivity of 70% to 85% when lesions are in the vesicular stage. Direct immunofluorescence for VZV antigen in lesions is the most sensitive rapid laboratory test. The virus is labile but can be isolated from vesicular fluid during the first 3 days of varicella in normal hosts and for up to 10 days in immunocompromised hosts or patients with disseminated zoster. Direct inoculation of vesicular fluid onto monolayers of cell culture (human embryonic lung fibroblasts) at the bedside increases the likelihood of isolation.

Treatment and Prevention

Live, attenuated varicella vaccine generates neutralizing antibody in more than 95% of recipients and also generates long-lived CD8⁺ cytotoxic T-cell responses against varicella virus.³⁰⁴ Vaccination of immunosuppressed children, including those with leukemia, is safe, although a small proportion of children will experience a mild, varicella-like clinical syndrome approximately 1 month after vaccination.³⁰⁵ In both healthy and immunosuppressed children, the vaccine is highly effective at preventing varicella, with efficacy rates of 50% to 90%. Two doses of varicella vaccine administered subcutaneously are recommended for children 12 months and older, adolescents, and adults without evidence of prior immunity.³⁰⁶ Second-dose catch-up vaccination is recommended for those who previously received only a single dose of vaccine.

A higher-dose live vaccine effectively re-stimulates virus-specific cellular immunity in adults and can reduce the frequency of reactivation, as well as the clinical severity of zoster.³⁰⁷ The high-dose live vaccine is recommended as a single dose in all healthy individuals 60 and older.³⁰⁸

Although uncomplicated varicella in children usually requires no specific treatment, oral acyclovir initiated within 24 hours of rash onset reduces the number of lesions, duration of fever, and healing time compared with placebo in children, adolescents, and adults.³⁰⁹ Sequential intravenous and oral acyclovir has been used in therapy of varicella in immunocompromised children.³¹⁰ In immunocompromised patients with localized zoster, intravenous acyclovir has been found to halt dissemination. In addition, oral acyclovir, valacyclovir, and famciclovir are effective for the treatment of zoster and may reduce the duration of postherpetic neuralgia in healthy adults.³¹¹ Intravenous acyclovir (10 mg/kg every 8 hours for 5 to 7 days) appears efficacious in varicella pneumonia in previously healthy adults if started early.³¹²

Key Points

- Viral infections, important causes of disease of the respiratory tract, are associated with substantial morbidity and mortality in all age groups.
- Clinical syndromes such as the common cold, pharyngitis, acute bronchitis, influenza-like illness, croup,

bronchiolitis, and pneumonia—may be caused by several different viruses, and most of the major respiratory viruses may cause more than one clinical syndrome.

- There is increasing recognition of the role of respiratory viruses in lower respiratory tract disease in immunocompromised individuals; the growing availability of molecular diagnostic tests will lead to many more viral diagnoses.
- Effective vaccines are available for the prevention of disease due to some viral pathogens, including influenza, measles, mumps, rubella, and varicella virus, and antiviral agents are available for some, including influenza, herpes viruses, cytomegalovirus, and varicella-zoster virus. For most respiratory viral pathogens, neither vaccines nor antivirals are currently available.
- New respiratory viruses are continually emerging at the interface between human and animal species. Recent examples include avian and swine influenza viruses, severe acute respiratory syndrome, Middle East respiratory syndrome, and hantavirus pulmonary syndrome. Continued surveillance for new agents is critical in controlling pandemics.

Vaccines
Smoking Cessation

An expanded version of this chapter is available online at ExpertConsult.

INTRODUCTION

Community-acquired pneumonia (CAP) is a frequent infectious respiratory disease.¹ Although many patients with CAP can be treated as outpatients, the mortality of CAP in those who do require hospitalization ranges from 5% to 15% and increases to 20% to 50% in patients who require intensive care unit (ICU) care. Hospital-acquired pneumonia (HAP) is the second most common and most frequently fatal nosocomial infection.

A clinical diagnosis of pneumonia can usually be established on the basis of signs, symptoms, and chest radiographs, although distinguishing CAP or HAP from conditions such as congestive heart failure, pulmonary embolism, and chemical aspiration pneumonia is sometimes difficult. Defining an etiologic agent is also challenging. Although early empirical therapy is necessary, it is important to identify the causative pathogen in patients who require hospitalization, both to confirm the appropriateness of therapy and to reduce unnecessary antimicrobial use.

Diagnosis and management of pneumonia has become more complex due to the growing number of aged and comorbid, debilitated, institutionalized, and immunocompromised individuals, to the diverse array of microorganisms that cause pneumonia, and to increasing antimicrobial resistance.

PATHOPHYSIOLOGY AND PATHOGENESIS

Aspiration of oropharyngeal or nasopharyngeal secretions is the main mechanism of contamination of lower airways by bacteria. While a person is awake, glottal reflexes prevent aspiration; during sleep, 50% of normal persons aspirate small volumes of pharyngeal secretions. Because oropharyngeal secretions may contain 10^7 to 10^{11} microorganisms per milliliter, aspiration of as little as 0.001 mL may carry more than 100,000 bacteria.

The oropharynx of healthy individuals is colonized by diverse microorganisms that vary in their potential virulence. The ability of microorganisms to colonize the oropharynx and to cause lower respiratory tract infections is determined in part by the interaction of specific microbial adhesins with cellular receptors. For example, *Streptococcus pneumoniae*, which contains multiple adhesions,² binds to the receptor for platelet-activating factor on epithelial cells, and this interaction is enhanced by cigarette smoke, infection with respiratory viruses, and particulate air pollutants,³⁻⁵ all of which are linked to increased risk for pneumococcal pneumonia. Likewise, *Staphylococcus aureus* expresses multiple adhesins that bind host extracellular matrix proteins.^{6,7} Gram-negative bacterial pathogens also possess specific adhesins, many of which form macromolecular structures, termed *pili*. *Klebsiella pneumoniae* exploits two distinct pili to adhere to epithelial cells: type 1 pili bind to diverse host target molecules with exposed mannose residues, and type 3 pili interact with extracellular matrix proteins.⁸

Several mechanisms in the airways prevent adherence and colonization by potential bacterial pathogens.

LESS COMMON CAUSES OF PNEUMONIA

Actinomycosis

Chlamydophila psittaci (Formerly *Chlamydia psittaci*)—Psittacosis

Coxiella burnetii—Q Fever

Nocardiosis

Melioidosis (*Burkholderia pseudomallei*)

Rhodococcus equi

Pulmonary Anthrax (*Bacillus anthracis*)

Tularemia (*Francisella tularensis*)

Plague (*Yersinia pestis*)

Moraxella catarrhalis

Neisseria meningitidis

Pasteurella multocida

Table 33-1 Common Causes of Community-Acquired Pneumonia in Patients Who Do Not Require Hospitalization*

Mycoplasma pneumoniae
Streptococcus pneumoniae
Chlamydophila pneumoniae
Haemophilus influenzae
Respiratory viruses

*Organisms are listed in the general order of frequency.

Respiratory epithelial cells synthesize and secrete peptides, termed *defensins* and *cathelicidins*, that possess broad-spectrum antimicrobial activity.⁹ In the distal airways and alveoli, pulmonary surfactant proteins A and C can inhibit bacterial binding to host cells and also promote phagocytosis of selected bacteria.^{10,11} The presence of complement and immunoglobulins (particularly *immunoglobulin A* [IgA]), also prevents colonization of the oropharynx. In addition to protection provided by host factors, the upper airway microbiota may modulate susceptibility to pathogens, as indicated by the evidence that broad-spectrum antimicrobial therapy predisposes to colonization and infection. The effects of the microbiota operate through competition for binding sites or nutritional resources, or by modulating expression of specific host defense molecules.¹²⁻¹⁵ Interactions between the virulence and quantity of aspirated or inhaled microorganisms and the individual's innate and adaptive immune responses determine whether pneumonia develops.¹⁶

As an alternative to aspiration of bacteria of the upper airways, *Mycoplasma pneumoniae*, *Chlamydophila* species, *Coxiella burnetii*, *Legionella*, and *Mycobacterium tuberculosis* enter the lower respiratory tract by inhalation. Inhalation pneumonia is most often due to microorganisms that survive suspended in the air for prolonged periods, are present in droplet nuclei smaller than 5 μm , and are able to evade innate immune responses.

EPIDEMIOLOGY

COMMUNITY-ACQUIRED PNEUMONIA

The true incidence of CAP is uncertain because the illness is not reportable and only 20% to 50% of patients require hospitalization. Estimates of the incidence of CAP range from 2 to 15 cases per 1000 persons per year, with substantially higher rates in older adults.¹⁷

Although the severity of disease is influenced by the patient's age and by the presence and type of coexisting conditions,¹⁸⁻²¹ the severity of disease is also related to the pathogen. *M. pneumoniae*, *S. pneumoniae*, *Chlamydophila pneumoniae*, *Haemophilus influenzae*, and viruses are causes of mild CAP (Table 33-1), whereas *S. pneumoniae*, *M. pneumoniae*, and *H. influenzae* can cause CAP severe enough to warrant hospitalization (Table 33-2).²¹⁻²³ The most frequently identified pathogens causing severe CAP (i.e., CAP requiring ICU care) include *S. pneumoniae*, enteric gram-negative bacilli, *S. aureus*, *Legionella pneumophila*, *M. pneumoniae*, *H. influenzae*, and respiratory viruses (Table 33-3).²¹⁻²⁵ Up to 20% of severe CAP episodes are caused by polymicrobial infection. Even if extensive diagnostic proce-

†Organisms are listed in the general order of frequency.

dures are performed, the responsible pathogen is not isolated in up to 50% to 60% of patients with severe CAP.

Gram-negative enteric bacilli, *S. aureus*, *Legionella* species, and respiratory viruses are uncommon causes of CAP, although local outbreaks can markedly increase the incidence of *Legionella*.^{26,27} Methicillin-resistant *Staphylococcus aureus* (MRSA), originally a nosocomial pathogen, has appeared in the community where it is referred to as *community-acquired MRSA*. Community-acquired MRSA can lead to severe pulmonary infections, including necrotizing and hemorrhagic pneumonia.²⁸ *Pseudomonas aeruginosa* infection is uncommon in the absence of specific risk factors (recent antibiotic treatment, *acquired immunodeficiency syndrome* [AIDS], and severe pulmonary comorbidity, especially bronchiectasis, cystic fibrosis, and severe *chronic obstructive pulmonary disease* [COPD]).^{21,22,24}

The likely etiology of severe CAP varies in differing patient populations, depending on age and comorbidities, including HIV infection.^{22,29-31a}

Age-Related Factors

Pneumonia remains one of the major causes of morbidity in children. In Europe, there are more than 2.5 million cases of childhood pneumonia yearly, which account for about 50% of hospital admissions for children. Radiographically defined pneumonia is present in 7.5% of febrile illnesses in infants up to 3 months old and in 13% of infectious illnesses during the first 2 years of life. In children younger than 2 years, *S. pneumoniae* and respiratory syncytial virus are the most frequent microorganisms, whereas *M. pneumoniae* is a leading cause of pneumonia in older children and young adults.

In adults, increased age is associated with a change in the distribution of microbial causes and an increase in the

frequency and severity of pneumonia.³² The annual incidence of CAP in noninstitutionalized older adults is estimated between 18 and 44 per 1000 compared with 4.7 to 11.6 per 1000 in the general population.^{17,32,33} Although older adults are particularly at risk for pneumococcal pneumonia, they also have increased rates of pneumonia due to group B streptococci, *Moraxella catarrhalis*, *H. influenzae*, *L. pneumophila*, gram-negative bacilli, *C. pneumoniae*, and polymicrobial infections.^{17,24,34} Although the absolute rate of infection by *M. pneumoniae* does not decrease with age, this pathogen accounts for a smaller proportion of pneumonia in older adults than in younger populations. In patients older than 80 years, there is a higher incidence of aspiration pneumonia and lower incidence of infection with *Legionella* species than in younger patients.³⁵

Personal Habits

Alcohol consumption is an important risk factor for CAP because of its potential to impair level of consciousness, thus increasing the risk for aspiration of oropharyngeal contents. In addition, diverse effects of alcoholism on innate and adaptive immunity have been reported, which may contribute to increased risk. Alcoholism has been shown to be an independent risk factor for increased rate and severity of pneumonia, especially that due to *S. pneumoniae*.^{36,37} This predisposition persists several months after cessation of alcohol consumption.³⁷

Smoking is one of the most important risk factors for CAP and is associated with an increased frequency of CAP due to *S. pneumoniae*, *L. pneumophila*, and influenza.³⁸ Smoking alters mucociliary transport and humoral and cellular defenses, affects epithelial cells, and increases adhesion of *S. pneumoniae* and *H. influenzae* to the oropharyngeal epithelium.⁴

Comorbidities

The most frequent comorbidity associated with CAP is COPD. Patients with COPD have an increased risk for CAP, due to alterations in mechanical and cellular defenses that allow bacterial colonization of the lower airways. Patients with severe COPD (forced expiratory volume in 1 second < 30% of predicted) and bronchiectasis have an increased risk for pneumonia caused by *H. influenzae* and *P. aeruginosa*.³⁸ In patients with COPD treated with oral corticosteroids for long periods, the risk for infection with *Aspergillus* species is increased.³⁹

Pneumonia remains the major cause of morbidity and mortality in patients with cystic fibrosis. During the first decade of life, *S. aureus* and nontypeable *H. influenzae* are the most common pathogens, although *P. aeruginosa* is occasionally isolated in infants. By 18 years of age, 80% of patients with cystic fibrosis harbor *P. aeruginosa* and 3.5% harbor *Burkholderia cepacia*.⁴⁰ *Stenotrophomonas maltophilia*, *Achromobacter xylosoxidans*, and nontuberculous mycobacteria are emerging pathogens in this population.⁴¹

Other comorbidities associated with increased rates of CAP and consequent mortality include congestive heart failure, chronic kidney or liver disease, cancer, diabetes, dementia, cerebrovascular diseases, and immunodeficiencies (e.g., neutropenia, lymphoproliferative diseases, immunoglobulin deficiencies, and human immunodeficiency virus [HIV] infection).⁴²⁻⁴⁴

Geographic and Occupational Considerations

Geographic factors, seasonal timing, travel history, and occupational or unusual exposures modify the risk of various microbial etiologies of CAP. For example, an increased frequency of *S. pneumoniae* is found in soldiers, painters, and South African gold miners. *Burkholderia pseudomallei* (melioidosis) is endemic in the rural tropics.⁴⁵ Exposure to pet birds or work on a poultry (especially turkey) farm or processing plant increases the risk of psittacosis (*Chlamydophila psittaci*), while contact with horses or other large mammals including cattle, swine, sheep, goats, or deer increases exposure to *Rhodococcus*. Rodent contact suggests the possibility of infection with *Yersinia pestis* (plague) in the rural southwestern United States⁴⁶ and *Francisella tularensis* (tularemia) in rural Arkansas or Nantucket, Massachusetts.⁴⁷ Exposure to sheep, dogs, and cats should prompt evaluation for *Coxiella burnetii* (Q fever).⁴⁸ The role of seasonal timing is illustrated by the increased incidence of lower respiratory tract infections due to *S. pneumoniae* and *H. influenzae* in winter months. Pneumonia causing the severe acute respiratory syndrome (SARS) due to a coronavirus emerged in epidemic form in Southeast Asia,^{49,50} and another coronavirus causes the emerging Middle East respiratory syndrome (MERS). Finally, the infectious agents that cause anthrax, tularemia, and plague may be used for bioterrorism or biowarfare purposes and cause lower respiratory tract infections.^{51,52}

HOSPITAL-ACQUIRED (NOSOCOMIAL) PNEUMONIA

Early-onset HAP (<5 days of hospitalization) is most often due to microorganisms that are also associated with CAP, such as *S. pneumoniae*, *H. influenzae*, and anaerobes. Late-onset HAP (>5 days of hospitalization) is mainly caused by MRSA, enteric gram-negative bacilli, *P. aeruginosa*, nonfermenters such as *Acinetobacter baumannii* and *S. maltophilia*, and polymicrobial infections.⁵³ Factors that increase the risk for HAP include antibiotic exposure, old age, severe comorbidities, underlying immunosuppression, colonization of the oropharynx by virulent microorganisms, conditions that promote pulmonary aspiration or inhibit coughing (e.g., thoracoabdominal surgery, endotracheal intubation, insertion of nasogastric tube, supine position), and exposure to contaminated respiratory equipment. A recent study suggests that multidrug-resistant microorganisms are more frequent in early-onset HAP than was initially thought⁵⁴ and that risk factors for early-onset pneumonia should be reappraised.

HEALTH CARE-ASSOCIATED PNEUMONIA

Health care now reflects a continuum with many traditional inpatient services provided in outpatient settings. Physicians often categorize new infections in such subjects as “community-acquired.” However, these health care-associated infections have a unique epidemiology more like that of hospital-acquired infections, and this has resulted in health care-acquired pneumonia (HCAP) being recognized as a separate entity by the American Thoracic Society (ATS) and Infectious Diseases Society of America (IDSA).⁵³ *S. aureus*

(both methicillin-sensitive and methicillin-resistant) and *P. aeruginosa* are the most frequent associated microorganisms. Compared with CAP, HCAP patients have more severe disease, higher mortality, greater length of hospital stay, and greater cost of care.⁵⁵

CLINICAL PRESENTATION

Pneumonia is characterized by the presence of fever, altered general well-being, and respiratory symptoms, such as cough (90%), sputum production (66%), dyspnea (66%), pleuritic pain (50%), and hemoptysis (15%). In older and immunocompromised patients, the signs and symptoms of pulmonary infection may be muted and overshadowed by nonspecific complaints. Temperature greater than 38.5° C or accompanied by chills should never be attributed to bronchitis without examining a chest radiograph.

Occasionally, there is a “classic” history, such as that of the patient with pneumococcal infection who presents with sudden onset of rigor followed by pleuritic chest pain, dyspnea, and cough with rusty sputum. Similarly, a patient with *Legionella* pneumonia may complain predominantly of diarrhea, fever, headache, confusion, and myalgia. For *M. pneumoniae* infection, extrapulmonary manifestations such as myringitis, encephalitis, uveitis, iritis, and myocarditis may be present. However, only rarely does the clinical history clearly suggest a specific etiologic diagnosis.

Information obtained from the clinical history and physical examination is not sufficient to confirm the diagnosis of pneumonia. A definitive diagnosis requires the finding of a new opacity on the chest radiograph.

In older patients, especially those with multiple comorbidities, pneumonia may present with general weakness, decreased appetite, altered mental status, incontinence, or decompensation due to underlying disease. The presence of tachypnea may precede other signs of pneumonia by 1 to 2 days. Tachycardia is another common initial sign but is less frequent and specific than tachypnea. Fever is absent in 30% to 40% of older patients. Owing to the lack of specific symptoms, the diagnosis of CAP is frequently delayed in older adults.^{17,34} Older patients with pneumonia who present with altered mental status without fever can have a delay in receiving antibiotics by more than 4 hours after arrival; this delay increases mortality.⁵⁶

TYPICAL VERSUS ATYPICAL PNEUMONIA

The division of CAP into typical and atypical syndromes has been used to predict the likely pathogens and select appropriate empirical therapy.¹⁸⁻²¹ The clinical picture of “typical” CAP is that of disease characteristically caused by bacteria such as *S. pneumoniae*, *H. influenzae*, and *K. pneumoniae*. The initial presentation is frequently acute, with an intense chill. Productive cough is present, and the sputum is purulent or bloody. Pleuritic pain may suggest *S. pneumoniae*. Physical examination reveals typical findings of pulmonary consolidation (see Chapter 16). Blood tests show leukocytosis with neutrophilia and the presence of band forms in most cases. Chest radiography shows lobar consolidation with air bronchograms (Fig. 33-1).

Figure 33-1 Pneumococcal pneumonia with lobar consolidation.

In contrast, the syndrome of gradual onset of fever, non-productive cough, and a relatively normal white blood cell count in a patient without a readily demonstrable bacterial pathogen has been called “atypical pneumonia.” Frequently, systemic complaints are more prominent than the respiratory ones. The atypical syndrome is characteristic of infections by pathogens such as *M. pneumoniae*, *Chlamydia* species, *C. burnetii*, and viruses. However, several studies, including one that included patients with mild CAP treated on an outpatient basis,⁵⁷ have found that neither the clinical symptoms nor the radiographic manifestations are sufficiently sensitive or specific to guide pathogen-directed antibiotic treatment against “typical” versus “atypical” microorganisms.⁵⁷ Therefore, current guidelines do not emphasize the use of the typical versus atypical classification to determine initial empirical antibiotic treatment for CAP.^{18-21,58}

PATIENT EVALUATION

CLINICAL EVALUATION

The clinical findings that best differentiate CAP from other acute respiratory tract infections are cough, fever, tachypnea, tachycardia, and pulmonary crackles; CAP is present in 20% to 50% of persons who have all five factors.⁵⁹ Specific signs of pulmonary consolidation are present in only one third of the cases that warrant hospitalization and are frequently absent in patients that are less ill. Early in the evolution of disease, pain and cough may be absent and the physical examination may be normal other than for fever. In debilitated older patients, vague clinical manifestations of pneumonia are common and the presence of fever with no apparent source, especially when accompanied by confusion or tachypnea, justifies obtaining a chest radiograph.

Clues to the etiologic diagnosis may lie outside the respiratory tract. Bradycardia in relation to the amount of fever (pulse should increase by 10 beats/min/ $^{\circ}\text{C}$ of temperature elevation) has been associated with pneumonia due to *Legionella*, *C. psittaci*, *Mycoplasma*, or *E. tularensis*. *M. pneumoniae* infection may present with extrapulmonary manifestations including arthralgia, cervical lymphadenopathy, bullous myringitis, diarrhea, myalgia, myocarditis, hepatitis, nausea, pericarditis, and vomiting.⁶⁰ Skin lesions of erythema multiforme or erythema nodosum suggest *Mycoplasma* infection (as well as tuberculosis and endemic fungal infection), whereas lesions of ecthyma gangrenosum are most often seen with *P. aeruginosa* infection. Finally, the examiner must look for the presence of complications such as pleural effusion, pericarditis, endocarditis, arthritis, and central nervous system involvement, which may necessitate further diagnostic procedures and, potentially, a change in therapy.⁶¹

LABORATORY EVALUATION

Once the patient is suspected to have pneumonia, laboratory studies should include blood cell counts, serum glucose and electrolyte measurements, and pulse oximetry or arterial blood gas assays.¹⁸⁻²¹ These data provide a basis for making decisions regarding the need for hospitalization. The increased incidence of CAP in HIV-infected individuals provides an additional rationale for HIV testing, particularly in patients with no other risk factors for CAP.

Marked leukocytosis with a leftward shift is more often encountered with infections caused by *S. pneumoniae*, *H. influenzae*, and gram-negative bacilli than with *M. pneumoniae*, *Chlamydia* species, *Coxiella*, or nonbacterial causes of pneumonia. Leukopenia may be seen with overwhelming pneumococcal or gram-negative bacillary pneumonia. The serum level of C-reactive protein and the erythrocyte sedimentation rate are increased to higher values with bacterial than with viral pneumonias. Thrombocytopenia and thrombocytosis are associated with a greater severity of pneumonia and higher mortality.

Procalcitonin (PCT), a precursor of calcitonin, is present at increased concentrations in the blood of persons with bacterial infections, and PCT assays have been used to evaluate the severity, prognosis, and evolution of pneumonia.⁶² Importantly, procalcitonin is used to deescalate antibiotics or to stop antibiotics when the levels decrease to a certain cutoff point.⁶³ A randomized trial of a PCT-guided strategy compared with a guideline-based algorithm, revealed equivalent primary outcomes of treatment of lower respiratory tract infections, but the PCT-guided strategy resulted in reduced antibiotic exposure and duration, fewer adverse effects of antibiotic treatment, and shorter length of stay.⁶⁴

RADIOGRAPHIC EVALUATION

Radiographic evaluation is necessary to establish the presence of pneumonia, because there is no combination of historical data, physical findings, or laboratory results that reliably confirms the diagnosis.^{18,21,59,65} Limitations of chest radiography include interobserver variability and suboptimal specificity, particularly in patients with the *acute respiratory distress syndrome* (ARDS).²¹ Conversely, the sensitivity

of the chest radiograph is decreased in (1) patients with emphysema, bullae, or structural abnormalities of the lung, who may present with delayed or subtle radiographic changes; (2) obese patients, in whom it may be difficult to discern the existence of pneumonia; and (3) patients with very early infection, severe dehydration, or profound granulocytopenia. *Computed tomography* (CT) of the chest provides a more sensitive means of detecting minor radiographic abnormalities.⁵⁹ However, a chest CT is not recommended for patients with suspected pneumonia who have an apparently normal chest radiograph.²¹

Although several radiographic patterns have been associated with pneumonia caused by specific microorganisms, the presence of a certain pattern is not a reliable method for diagnosing a specific pathogen.^{66,67} Nonetheless, the presence of air bronchograms and a lobar (eFig. 33-1) or segmental pattern is more characteristic of typical than atypical causes of pneumonia. In contrast, a mixed pattern (alveolar and interstitial disease (eFig. 33-2) is more frequently observed with atypical pneumonias. Pneumonia complicating aspiration (frequently from anaerobes) (eFig. 33-3) most often involves the superior segment of the right lower lobe or posterior segment of the right upper lobe, or both, as well as the corresponding segments on the left. Infections developing from hematogenous seeding often appear as multiple rounded, small opacities, sometimes with cavities, with a basal predominance, where the distribution of blood flow is greatest. Demonstration of a lung abscess (eFig. 33-4), cavitation, or necrotizing pneumonia suggests infection by anaerobes, *S. aureus*, *Streptococcus pyogenes*, or gram-negative bacilli. Pleural effusion frequently accompanies pneumonia; the size of the pleural effusion on the chest radiograph helps determine whether thoracentesis should be performed.

MICROBIOLOGIC EVALUATION

Identification of the infecting microorganism facilitates the use of specific therapy instead of unnecessarily broad-spectrum antimicrobial agents. Although the utility of sputum examination is debated (see later), pleural fluid (if present) and two sets of blood cultures should be obtained in patients hospitalized for CAP. Optimal culture results require that specimens be obtained before initiation of antimicrobial therapy. Sputum samples must be carefully collected, transported, and processed in order to optimize the recovery of common bacterial pathogens. These recommendations are summarized in Tables 33-4 and 33-5.

Sputum Examination

Microscopic examination of expectorated sputum is the easiest and most rapidly available method of evaluating the microbiology of lower respiratory tract infections. A valid expectorated sputum specimen can be obtained in about 40% of patients hospitalized with CAP. When interpreting sputum cultures, it is crucial to ensure that oropharyngeal contents do not unduly contaminate the specimens. The presence of more than 10 squamous epithelial cells per low-power field ($\times 100$ magnification) indicates excessive oropharyngeal contamination and the specimen should be discarded because it is not representative of the pulmonary milieu.¹⁸ A specimen with few or no squamous cells and

Table 33-4 Recommended Microbiologic Evaluation in Patients with Community-Acquired Pneumonia

PATIENTS WHO DO NOT REQUIRE HOSPITALIZATION

None*

PATIENTS WHO REQUIRE HOSPITALIZATION

Two sets of blood cultures (obtained prior to antibiotics)
Gram stain and culture of a valid sputum sample
Urinary antigen test for detection of *Legionella pneumophila* (in endemic areas or during outbreaks)
Stain for acid-fast bacilli and culture of sputum (if tuberculosis is suggested by clinical history or radiologic findings)
Fungal stain and culture of sputum, and fungal serologies (if infection by an endemic mycosis is suggested by the clinical history or radiologic findings)
Sputum examination for *Pneumocystis jirovecii* (if suggested by clinical history or radiologic findings)
Nucleic acid amplification tests for *Mycoplasma pneumoniae*, *Chlamydomphila pneumoniae*, *Chlamydomphila psittaci*, *Coxiella burnetii*, *Legionella* species, and respiratory viruses (in endemic areas or during outbreaks)
Culture and microscopic evaluation of pleural fluid (if significant fluid is present)

ADDITIONAL TESTS FOR PATIENTS WHO REQUIRE TREATMENT IN AN ICU

Gram stain and culture of endotracheal aspirate or bronchoscopically obtained specimens using a protected specimen brush or BAL
Other procedures as for other hospitalized patients

*Gram stain and culture should be strongly considered in patients with risk factors for infection by an antimicrobial-resistant organism or unusual pathogen.

BAL, bronchoalveolar lavage; ICU, intensive care unit.

Table 33-5 Recommended Microbiologic Evaluation in Patients with Hospital-Acquired Pneumonia

Two sets of blood cultures
Gram stain and culture of a valid sputum sample*
Urinary antigen test for detection of *Legionella pneumophila* (in endemic areas or during outbreaks)

*Gram stain and culture of valid sputum sample, endotracheal aspirate, or bronchoscopically obtained specimens using a protected specimen brush or bronchoalveolar lavage (if patient is intubated).

many polymorphonuclear white blood cells (>25 cells/low-power field in a sample from a patient who is not granulocytopenic⁶⁸) is ideal (see Fig. 33-3). Gram-stained expectorated sputum specimens of acceptable quality should be carefully examined using ×1000 magnification (oil immersion objective). Specific fluorescent antibodies are used to evaluate sputum or other respiratory tract specimens for the presence of *Legionella* and selected other pathogens (see Chapter 17).

When acceptable sputum is obtained, the specificity of the Gram stain for pneumococcal pneumonia is estimated to be greater than 80%.⁶⁹ Because the fastidious nature of *S. pneumoniae* and *H. influenzae* leads to the death of these organisms, the sensitivity of sputum culture may be lower than that of sputum Gram stain examination for *S. pneumoniae* or *H. influenzae*. In contrast, *S. aureus* and gram-negative bacilli may dominate even if they are not the cause of the patient's illness, because these bacteria are hardier and may proliferate during sample transport and processing. True pneumonia due to *S. aureus* or gram-negative bacilli is doubtful if the Gram stain of a valid sputum speci-

men does not corroborate the presence of these bacteria. In good quality Gram-stained sputum, the presence of a single or a preponderant morphotype of bacteria (≥90%) is considered diagnostic. In the absence of an informative Gram stain, the predictive value of sputum culture is very low.

The latest IDSA/ATS guidelines⁵⁸ recommend obtaining a sputum sample for Gram stain and culture in hospitalized patients with the clinical indications listed in Table 33-6 but are optional for patients without these conditions.

For patients with HAP or ventilator-associated pneumonia (VAP), the range of potential pathogens is so broad and antimicrobial susceptibility patterns so diverse that vigorous diagnostic measures are justified. In ventilated patients, the equivalent of sputum is the endotracheal aspirate for which the criteria for validity are the same as those for sputum. Although the Gram stain and qualitative cultures of endotracheal aspirates have excellent sensitivity, they have poor specificity.⁷⁰ Quantitative cultures of endotracheal aspirate samples may help distinguish colonization from infection. However, there has been difficulty in choosing a quantitative threshold for VAP; some have chosen to consider a range of quantitative cultures, from 10³ to 10⁶ CFU/mL, rather than a single cutoff.⁷¹

Some bacterial agents of pneumonia cannot be cultivated on conventional laboratory media. For example, *Legionella* requires buffered charcoal yeast extract agar for isolation, whereas recovery of *Chlamydomphila* species and *C. burnetii* requires culture in mammalian cell lines. When necessary, specimens can be sent to specialized or reference laboratories for appropriate procedures. Culture of certain agents of bacterial pneumonia poses major health risks to laboratory workers (e.g., *E. tularensis*, *Bacillus anthracis*, *C. burnetii*). Specimens suspected to harbor one of these agents should be dealt with carefully in a biologic safety hood, and isolation of the pathogens should be reserved for specialized laboratories.

Blood and Pleural Fluid Cultures

Although the overall yield of blood cultures is less than 20% in patients hospitalized for CAP, a positive culture of blood or pleural fluid establishes the etiologic diagnosis of pneumonia.^{72,73} Not surprisingly, the detected rate of bacteremia is lower in patients with mild CAP and higher in patients

with severe CAP, especially those warranting ICU care. Prior antibiotic treatment decreases the yield of blood cultures.⁷⁴ The latest IDSA/ATS guidelines⁵⁸ recommend obtaining blood samples for culture in hospitalized patients with the clinical indications listed in Table 33-6 but are optional for patients without these conditions.

In up to 40% of CAP cases, a pleural effusion may be present. Although the specificity of pleural exudate cultures is very high, the sensitivity is low because of the low incidence of invasion of the pleura. Diagnostic thoracentesis should be performed when a significant pleural effusion is present. Gram stain of pleural fluid may produce an indication of the infecting organisms within 1 hour, while culture identification may require 24 to 48 hours.

Antigen Detection

Commercial assays can be used to detect capsular polysaccharide antigens of *S. pneumoniae* or *L. pneumophila* serogroup 1 in urine, and can require less than 1 hour.^{69,74,75} The sensitivity of these tests is little affected by prior antibiotic treatment; indeed, results may remain positive several weeks after successful treatment. For *L. pneumophila* serogroup 1, the sensitivity is 60% to 80%, and the specificity is greater than 95%.⁷⁶ Urinary antigen testing is currently the most helpful rapid test for the diagnosis of *Legionella* infections. The major limitation of urinary antigen tests is that currently available tests are intended to detect *L. pneumophila* serogroup 1 antigen only, although this is the most common cause of *Legionella* infection.

The sensitivity of *S. pneumoniae* urinary antigen detection is 50% to 80% and the specificity is 90%.⁷⁷ The degree of positivity for the *S. pneumoniae* urinary antigen test correlates with the *Pneumonia Severity Index* (PSI).⁷⁸ The *S. pneumoniae* antigen test may also be applied on pleural fluid with a sensitivity and specificity of almost 100%. Urine specimens of children, frequent carriers of *S. pneumoniae* in the nasopharynx, may test positive in the absence of evidence of pneumonia, and the test should therefore be interpreted with caution in children.⁷⁹ The most recent IDSA/ATS guidelines⁵⁸ recommend *S. pneumoniae* and *L. pneumophila* urinary antigen detection in hospitalized patients with the clinical indications listed in Table 33-6, but are optional for patients without these conditions.

Antigens for the many common respiratory viruses, influenza virus, respiratory syncytial virus, adenovirus, and parainfluenza viruses can be detected by direct immunofluorescence or by enzyme-linked immunoassay. A rapid antigen detection test for influenza can provide an etiologic diagnosis within 15 to 30 minutes. Test performance varies according to the test used, viral strain, sample type, duration of illness, and patient age. Most show a sensitivity ranging from 50% to 70% and a specificity approaching 100% in adults (see Chapter 17).

Nucleic Acid Amplification Tests

Culture procedures for viruses and fastidious bacteria, *M. pneumoniae*, *C. pneumoniae*, *L. pneumophila*, and *Bordetella pertussis*, which normally do not colonize in the human respiratory tract, are too insensitive and too slow to be helpful in guiding therapy. These pathogens should be detected by nucleic acid amplification tests; their sensitivity is generally superior to that of the traditional procedures

and some are considered as the “gold standard.”⁸⁰ Real-time multiplex polymerase chain reaction assays detect respiratory viruses in both immunocompetent and immunosuppressed hosts.⁸¹ (See Chapter 17 for detailed information on nucleic acid amplification tests for respiratory pathogens.)

Serologic Evaluation

Before the development of nucleic acid amplification tests, serologic techniques were used to establish a microbiologic diagnosis for pneumonia caused by pathogens that cannot be readily cultured. Examples include common pathogens such as *M. pneumoniae*, *C. pneumoniae*, and *L. pneumophila*, and less common causes of pneumonia such as those caused by the agents of tularemia, brucellosis, and psittacosis, and certain viruses. Diagnosis usually requires that a convalescent specimen demonstrate a fourfold increase in immunoglobulin (Ig) G titer above that present in an acute specimen. These tests are not helpful in initial patient management but are of utility in defining the epidemiology of the pertinent infectious agents. Because IgM antibodies appear earlier than IgG antibodies, the detection of pathogen-specific IgM in serum has been used for the early serologic diagnosis of certain acute infections.

INVASIVE DIAGNOSTIC TECHNIQUES

Because of problems encountered with the use of expectorated sputum, it may be necessary to perform an invasive procedure to obtain suitable material for microscopy and cultures. This may be important in the management of patients with life-threatening CAP in whom diagnostic materials cannot otherwise be obtained, patients with progressive pneumonia despite seemingly appropriate antimicrobial therapy, immunocompromised patients, and patients with HAP, especially in the setting of endotracheal intubation.^{61,82} Although qualitative culture of materials obtained by endotracheal suction has excellent sensitivity, the specificity of such cultures is poor; thus, overreliance on these cultures can lead to antibiotic overtreatment.⁷¹

Bronchoscopic Samples

The reliability of bronchoscopic procedures to determine the microbial etiology of pneumonia depends on the technique used and the organism sought. When compared with sputum cultures, optimally processed bronchoscopic specimens demonstrate improved sensitivity and equal specificity for the culture of pathogenic fungi and mycobacteria. However, such materials have unacceptably poor specificity for routine bacterial cultures owing to oropharyngeal contamination. Semiquantitative or quantitative cultures of materials obtained bronchoscopically with a protected sheath brush or through *bronchoalveolar lavage* (BAL) and by direct lung aspiration have been successfully used for aerobic and anaerobic bacterial cultures⁸³⁻⁸⁵ (see Chapters 17 and 22). For protected sheath brush cultures, a threshold of 10^3 colony-forming units (CFU)/mL has been recommended to distinguish colonization from infection. However, 14% to 40% of duplicate samples yield disparate quantitative results.

BAL fluid can be quantitatively cultured for bacteria and qualitatively cultured for fungi, mycobacteria, and viruses. A concentrate can be stained for cytochemical and

fluorescence evaluation.⁸⁵ In one study, the threshold of 10^3 CFU/mL for diagnosing bacterial pneumonia correlated well with diagnoses based on protected sheath brush results and histologic examination of the lung.⁸⁶ BAL permits identification of contaminated specimens (i.e., those with greater than 1% squamous epithelial cells), the immediate diagnosis of infection (i.e., intracellular bacteria in more than 2% to 5% of examined polymorphonuclear leukocytes), and the exclusion of infection (i.e., the absence of bacterial pathogens in culture of BAL fluid, although the sensitivity is reduced by prior antibiotic administration).^{87,88}

In one study, the use of quantitative cultures obtained by protected sheath brush and BAL, compared with qualitative cultures of endotracheal aspirates and clinical evaluation, was associated with lower 14-day mortality rates, earlier reversal of organ dysfunction, and less antibiotic use.⁸⁹ However, other randomized trials on the use of quantitative cultures of protected sheath brush and BAL specimens, rather than quantitative cultures of endotracheal aspirates, in patients with VAP have not replicated these findings.^{90,91} The use of a sophisticated algorithm (i.e., Clinical Pulmonary Infection Score) increases the diagnostic accuracy of clinical judgment.⁹²

Transthoracic Lung Aspiration

Transthoracic lung aspiration obtains specimens suitable for microbiologic and cytologic examination directly from lung parenchyma (eFig. 33-5). It is more widely used for diagnosing malignant pulmonary lesions than infectious diseases, for which, in immunocompetent hosts, the diagnostic yield by transthoracic lung aspiration is approximately 50%. Serious complications of transthoracic lung aspiration include pneumothorax and hemoptysis, even when small-gauge needles are used.

DIFFERENTIAL DIAGNOSIS

Several diseases may present with fever and chest radiographic opacities and mimic CAP (eTable 33-1)⁵⁹; such diseases should be suspected when the radiographic resolution is unusually quick or when there is a lack of response to initial or subsequent antibiotic treatments. In patients with HAP, and particularly in those with VAP, the classic signs and symptoms of pneumonia (including new radiographic changes, fever, leukocytosis or leukopenia, and purulent pulmonary secretions) are neither sufficiently sensitive nor specific to confirm the presence of a pulmonary infection. Atelectasis, pulmonary hemorrhage, ARDS, and pulmonary embolism, among others, are conditions that may mimic pneumonia. In patients with suspected HAP or VAP, the microbiologic confirmation of pneumonia is important in order to avoid unnecessary treatments and increased antibiotic resistance.

THERAPEUTIC APPROACH TO PNEUMONIA

Once the diagnosis of pneumonia is made, the clinician must decide the appropriate treatment setting: outpatient, general hospital bed, or ICU. Applying prediction rules can

facilitate this decision. The second key initial decision is the selection of initial antimicrobial therapy.

ASSESSMENT OF SEVERITY

The PSI (eTable 33-2) is a scoring system derived from a retrospective analysis of a cohort of 14,199 patients with CAP and prospectively validated in a separate cohort of 38,039 patients with CAP.⁹³ The PSI is heavily weighted by age, which means it is less useful at extremes of age and is not valid in children. Outpatient treatment is recommended for patients with a PSI score of 70 or less (class I or II). Patients with a PSI score of 71 to 90 (class III) may benefit from brief hospitalization, while inpatient care is appropriate for patients with a score greater than 90 (class IV and V). Prospective studies in both community and teaching hospitals demonstrate that the hospital admission decisions based on PSI may be safely and effectively applied in clinical practice.⁹⁴⁻⁹⁶ The PSI is complex and often needs decision support tools for efficient use in a busy emergency department.

The British Thoracic Society validated the simpler CURB-65 score for admission triage decisions.^{25,97} Their algorithm assigns 1 point for each of the following findings at presentation: (1) confusion; (2) urea higher than 7 mmol/L (equal to BUN more than 20 mg/dL); (3) respiratory rate of 30/min or more; (4) low systolic (<90 mm Hg) or diastolic (≤ 60 mm Hg) blood pressure; and (5) age 65 years or older. Outpatient treatment is recommended for 0-1 points, brief inpatient or supervised outpatient care is recommended for 2 points, and hospitalization is recommended for 3 or greater, with consideration of ICU care for patients with scores of 4 or 5.

Risk stratification for both PSI and CURB-65 was based on associated mortality. They are therefore not sensitive to logistic and social issues such as reliability of oral intake, including antibiotics, and home support.

Patients initially admitted to a general floor with subsequent transfer to the ICU have higher mortality than patients with equivalent severity of illness admitted directly to the ICU.⁹⁸ Neither PSI nor CURB-65 are accurate for determining need for ICU care in patients without an obvious indication such as the need for mechanical ventilation or vasopressor support while still in the emergency department. Several scores have been developed for this critical decision.^{58,99-101} These scores share many common risk factors (Table 33-7) and appear to be equally effective,¹⁰² and management of severe CAP per these guidelines has been associated with decreased mortality.¹⁰³⁻¹⁰⁵ The optimal use of these scores is to identify at-risk patients who need additional evaluation or monitoring even if not initially admitted to the ICU.

SELECTION OF ANTIMICROBIAL AGENTS

Whenever possible, treatment for pneumonia should use the antibiotic with the narrowest spectrum possible, selected on the basis of the underlying pathogen. However, pathogens are rarely identified at the time of presentation, especially when pneumonia is managed in the outpatient setting. Because optimal outcomes are associated with a rapid initiation of antibiotics, initial treatment for patients

Patient Characteristic	Points Assigned
DEMOGRAPHIC FACTORS	
Males	Age (yr)
Females	Age (yr) – 10
Nursing home residents	Age (yr) + 10
COMORBID ILLNESSES	
Neoplastic disease	+30
Liver disease	+20
Congestive heart failure	+10
Cerebrovascular disease	+10
Renal disease	+10
PHYSICAL EXAMINATION FINDINGS	
Altered mental status	+20
Respiratory rate 30/min or greater	+20
Systolic blood pressure <90 mm Hg	+20
Temperature <35° C or ≥40° C	+15
Pulse 125/min or greater	+10
LABORATORY FINDINGS	
pH <7.35	+30
BUN >10.7 mmol/L	+20
Sodium <130 mEq/L	+20
Glucose >13.9 mmol/L	+10
Hematocrit <30%	+10
PO ₂ <60 mm Hg or O ₂ saturation <90%	+10
Pleural effusion	+10

*A risk score is obtained by summing the patient's age in years (age – 10 for females) and the points for each applicable patient characteristic. Patients with a score <50 are candidates for outpatient treatment, whereas those with scores >90 warrant hospitalization. Proper management of patients with scores of 70 to 90 requires careful application of clinical judgment. BUN, blood urea nitrogen; PO₂, oxygen pressure.

with pneumonia must be empirical. In selecting initial empirical antimicrobial therapy, physicians should consider the setting in which the pneumonia arose (e.g., community, hospital, nursing home), the severity of illness, age of the patient, presence of comorbidities and immunosuppression, recent antimicrobial therapy, and specific clinical manifestations of the illness. Geographic and facility-specific factors, such as the local prevalence of specific microorganisms (e.g., *C. burnetii*, *L. pneumophila*, endemic mycoses, and multidrug-resistant [MDR] pathogens), may also affect the initial treatment choice.

In hospitalized patients, specimens for cultures of blood, sputum, and pleural fluid (if present) should be obtained before treatment. A brief delay in starting therapy while performing diagnostic procedures is reasonable in patients who are not hypotensive. However, delays of more than 4 to 8 hours may increase the length of hospitalization and have been associated with increased mortality.^{106,107}

Community-Acquired Pneumonia

The standard therapy for inpatient empirical antibiotic coverage of CAP is one of two regimens: the combination of a second- or third-generation cephalosporin combined with a macrolide or one of the fluoroquinolones with efficacy against respiratory pathogens (levofloxacin, moxifloxacin, gatifloxacin).⁵⁸ Either therapy should be effective against penicillin-resistant *S. pneumoniae*.¹⁰⁸ The North American guidelines^{20,21,58} recommend that any empirical regimen for CAP should be active against “atypical” pathogens such as *M. pneumoniae*, *C. pneumoniae*, and *L. pneumophila*. Retrospective analyses of patients hospitalized with CAP indicate that regimens that cover “atypical” pathogens and those that follow recommendations made by the ATS and the IDSA are associated with improved clinical outcomes.^{18,20,96,109,110} In contrast, some Northern European guidelines suggest atypical coverage is not needed unless

patients have clinical features more common to atypical pathogens.⁹⁷ It is important to recognize that all CAP treatment guidelines are based on broad epidemiologic considerations that may vary by location. Variation from these regimens should be based on specific epidemiologic or clinical characteristics that strongly suggest one of the less common CAP pathogens such as mixed aerobic-anaerobic flora due to aspiration or presence of gram-negative Enterobacteriaceae or *P. aeruginosa* in patients with specified risk factors.^{24,111}

When tuberculosis is a possibility, fluoroquinolones should be used cautiously in CAP, because as little as 10 days of fluoroquinolone administration is sufficient to select for fluoroquinolone-resistant *M. tuberculosis*.¹¹²

The greatest factor to consider in the choice of regimens is a history of recent use of any of the agents.¹¹³ Widespread fluoroquinolone use, especially in subtherapeutic doses, and use of ciprofloxacin has been associated with fluoroquinolone resistance in up to 13% of *S. pneumoniae* isolates in Hong Kong.¹¹⁴ Fluoroquinolone resistance and subsequent treatment failures are reported in pneumococcal CAP,¹¹⁴⁻¹¹⁶ but this is less common with use of the fluoroquinolones that have improved activity against respiratory pathogens. In contrast, the frequency of macrolide resistance in *S. pneumoniae* is increasing, and a macrolide should not be used for monotherapy of *S. pneumoniae* infection unless in vitro testing confirms that the patient's strain is susceptible to macrolides.

Empirical antibiotic treatment of severe CAP (SCAP) remains controversial, predominantly due to a lack of treatment studies specifically focused on SCAP. The spectrum of etiologies is clearly greater in SCAP. Even so, penicillin-sensitive pneumococci are still the most likely etiology. Whether SCAP justifies more aggressive diagnostic testing or broader spectrum empirical treatment in all cases has not been established. Retrospective studies suggest combination therapy specifically for severe pneumococcal pneumonia and for SCAP in general are associated with lower mortality. In a large cohort of older patients with CAP needing hospitalization, antibiotic treatment including azithromycin was associated with a lower 90-day risk mortality compared with other antibiotics.^{116a}

Hospital-Acquired Pneumonia and Ventilator-Associated Pneumonia

Empirical therapy for VAP is necessarily broad because the range of potential pathogens is large and mortality is increased when the responsible pathogen is resistant to the initial empirical antibiotic regimen (Table 33-8). Recommended empirical regimens include expanded-spectrum β-lactam agents, usually in combination with aminoglycosides and with MRSA coverage.⁵³ The empirical β-lactam should be based on antibiotic sensitivity patterns for common gram-negative pathogens in the relevant institution or specific unit.

Empirical antibiotics for HAP are less well studied. HAP in nonintubated patients is a mixture of CAP pathogens and the pathogens found in VAP, although the frequency of the latter is likely lower, especially in cases that present early after admission. The greatest risk for MDR pathogens in nonintubated patients with HAP is recent antibiotic therapy, and monotherapy is probably adequate for most patients

Summaries of the recent IDSA/ATS guideline CAP antibiotic recommendations are presented in eTable 33-3 and eTable 33-4, respectively.⁵⁸

[†]Advanced macrolides are azithromycin and clarithromycin.[‡]Modifying factors include those considered to increase the risk of infection by a penicillin-resistant pneumococcus (age older than 65 years, exposure to a β -lactam antimicrobial within the prior 3 months, alcoholism, prior immunosuppressive therapy, multiple medical comorbidities, exposure to a child in a daycare center or to infection by an enteric gram-negative bacillus (residence in a nursing home, underlying cardiopulmonary disease, multiple comorbidities, or recent antimicrobial therapy).[§]Preferred regimen may be determined by whether the patient has received antibiotics within the prior 3 months.^{||}Antianaerobic agents include clindamycin, metronidazole, and β -lactam/ β -lactamase inhibitor combinations.[¶]Acceptable cephalosporins include second-generation agents (e.g., cefuroxime, cefamandole), third-generation agents (cefotaxime or ceftriaxone), or fourth-generation agents (cefepime or ceftazidime, neither of which is available in the United States).

**Second-choice agent.

^{††}American Thoracic Society risk factors for *Pseudomonas aeruginosa* are structural lung disease (i.e., bronchiectasis, cystic fibrosis), corticosteroid use (>10 mg prednisone/day), broad-spectrum antibiotic therapy for more than 7 days in the past month, or malnutrition. The Infectious Diseases Society of American risk factors for *P. aeruginosa* include only structural lung disease or recent completion of a course of antibiotics or steroids. The Canadian risk factors include only structural lung disease, recent antibiotic therapy, or recent hospitalization in an intensive care unit.^{††}Antipseudomonal β -lactams include ceftazidime, cefepime, imipenem, meropenem, mezlocillin, piperacillin, and piperacillin-tazobactam.

Table 33-8 Guidelines for Empirical Antibiotic Treatment of Nosocomial Pneumonia*

Setting	Core Pathogens	Antimicrobial Choices
2 TO 5 DAYS IN HOSPITAL Mild to moderate pneumonia [†] Severe pneumonia “low-risk” [†]	Enterobacteriaceae <i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> Methicillin-sensitive <i>Staphylococcus aureus</i>	β-Lactam/β-lactamase inhibitor [‡] or ceftriaxone or fluoroquinolone [§] All ± an aminoglycoside
≥5 DAYS IN HOSPITAL Mild to moderate pneumonia	As above	As above
≥5 DAYS IN HOSPITAL Severe HAP “low risk”	<i>Pseudomonas aeruginosa</i> <i>Enterobacter</i> spp. <i>Acinetobacter</i> spp.	Carbapenem or β-lactam/β-lactamase inhibitor [‡] or cefepime All plus amikacin or fluoroquinolone [§]
≥2 DAYS IN HOSPITAL Severe HAP “high risk”	As above	As above
SPECIAL CIRCUMSTANCES ^{19,58}		
Recent abdominal surgery or witnessed aspiration	Anaerobes	As per Table 33-9
Other sites of infection with MRSA or prior use of antistaphylococcal antibiotics	MRSA	As per Table 33-9
Prolonged ICU stay or prior use of broad-spectrum antibiotics or structural lung disease (cystic fibrosis, bronchiectasis)	<i>P. aeruginosa</i>	As per Table 33-9
Endemicity within facility and either impaired cell-mediated immunity or failure to respond to antibiotics	<i>Legionella</i>	As per Table 33-9

*High-risk criteria include age older than 65 years, pancreatitis, chronic obstructive pulmonary disease, central nervous system dysfunction (stroke, drug overdose, coma, status epilepticus), congestive heart failure, malnutrition, diabetes mellitus, endotracheal intubation, renal failure, complicated thoracoabdominal surgery, and alcoholism. All other patients are considered to be at low risk.

This protocol does not address the treatment of neutropenic or HIV-infected persons.

Severe pneumonia requiring care in an ICU is characterized by rapid radiographic progression, multilobar disease, or cavitation. All other cases of nosocomial pneumonia are considered *mild to moderate*.

[†]Antimicrobial treatment should also be sufficient to cover core pathogens.

[‡]Ticarcillin-clavulanate and piperacillin-tazobactam are the preferred β-lactam/β-lactamase inhibitors for the treatment of nosocomial pneumonia. Ampicillin-sulbactam lacks adequate activity against many nosocomial enteric gram-negative bacilli.

[§]Levofloxacin (IV or PO), gatifloxacin (IV or PO), moxifloxacin (IV or PO), or gemifloxacin (PO only) are preferred for *Streptococcus pneumoniae*. When used for severe HAP, levofloxacin should be dosed at 750 mg IV daily. Ciprofloxacin has the best in vitro activity against *Pseudomonas aeruginosa*.

HAP, hospital-acquired pneumonia; ICU, intensive care unit; MRSA, methicillin-resistant *Staphylococcus aureus*.

Modified from American Thoracic Society: Hospital-acquired pneumonia in adults: Diagnosis assessment of severity, initial antimicrobial therapy, and preventative strategies. *Am J Respir Crit Care Med* 153:1711–1725, 1995.

without recent antibiotic exposure. Anaerobes appear to play a slightly greater role in HAP than VAP because of the risk of macroaspiration, but specific anaerobic coverage is not necessary if an appropriate β-lactam is used. Unless *Legionella* is known to be endemic in the institution, targeted therapy for this pathogen is seldom necessary in the empirical treatment of HAP. Efforts to identify the cause of infection are especially crucial in patients with HAP or VAP, to allow selection of optimal antimicrobial therapy and minimize the duration of empirical broad-spectrum coverage.

Health Care–Associated Pneumonia

The optimal approach to empirical coverage for HCAP remains controversial, due to variations in health care systems and definitions.^{55,117–119} Pneumonia in nursing home and chronic care facility residents is seen in a bimodal pattern. Ambulatory patients who are able to take care of most of their activities of daily living have disease that resembles CAP,²⁹ while in contrast, severely debilitated patients with tracheostomies, feeding tubes, frequent and recent acute care hospital admissions, and frequent

exposure to antibiotics are at high risk for MDR pathogens and should be treated with VAP regimens. Culture-negative HCAP patients have equivalent or better outcomes when treated with CAP antibiotics as with broader spectrum treatment,¹¹⁹ but are difficult to identify at admission. If started on broader therapy, deescalation to CAP therapy after culture results return negative appears safe.¹²⁰

Other Pneumonia Syndromes

On initial presentation, a variety of other infectious pulmonary syndromes may not be readily differentiated from acute bacterial pneumonia. Examples include influenza A, severe acute respiratory syndrome,^{49,50} hantavirus pulmonary syndrome, and other viral pneumonias. Milder cases of viral pneumonia may be distinguished by a low PCT level and antibiotics can be safely withheld or withdrawn in these patients.¹²¹

Concerns about potential bioterrorism or biowarfare require attention to the epidemiologic, clinical, and microbiologic significance of pneumonia due to *B. anthracis* (anthrax),⁵¹ *E. tularensis* (tularemia),⁵² and *Y. pestis* (plague). These infectious agents are individually discussed later in

this chapter. Further information may be obtained from organizations such as the Centers for Disease Control and Prevention (www.cdc.gov), IDSA (www.idsociety.org), and the World Health Organization (www.who.org) (see Chapter 40).

ADJUSTMENTS IN ANTIMICROBIAL THERAPY

If the etiologic agent of a patient's pneumonia has been identified, the initial antimicrobial regimen should be adjusted based on the results of in vitro susceptibility testing. The ideal drug for a known pathogen has the narrowest spectrum of activity and is the most efficacious, least toxic, and least costly. Pathogen-based modification of therapy is particularly important in HAP because prolonged use of broad-spectrum empirical agents promotes the emergence of MDR pathogens. Recommendations for specific drug choices for specific microorganisms are discussed under the sections devoted to individual microorganisms and are summarized in Table 33-9. If a pathogen is not identified, reevaluation of the initial therapeutic regimen must take into account the patient's response to therapy. Change from parenteral to oral antimicrobial therapy can safely be made in hospitalized CAP patients when clinically stable and able to absorb effective oral antimicrobials^{122,123}; this is often achieved within 3 days. In-hospital observation after switching from intravenous to oral antibiotics for CAP patients is not needed. Because HAP pathogens are frequently resistant to available oral antimicrobials, enteral absorption is less predictable, and the severity of illness is greater, initial oral antimicrobial therapy is much less frequently appropriate.

COMMON CAUSES OF PYOGENIC PNEUMONIA

Individual pneumonia pathogens may have unique epidemiology, diagnostic tests, and/or treatment. The sections that follow emphasize these unique aspects for selected pathogens (or groups).

STREPTOCOCCUS PNEUMONIAE (PNEUMOCOCCAL PNEUMONIA)

Epidemiology

S. pneumoniae is the most frequent cause of CAP among patients who require hospitalization.^{21,22} The overall incidence of pneumococcal pneumonia is approximately 200 cases per 100,000 persons per year, with 9 to 14 cases per 100,000 cases of bacteremia. This infection accounts for 40,000 deaths annually in the United States with most deaths in the very young and the elderly. Risk factors, particularly in adults, include cigarette smoking, HIV infection (even with preserved CD4 counts), heavy alcohol use, chronic liver disease, genetic defects in host immunity, and malnutrition.^{124,125} Pneumococcal infections present predominantly in the winter and early spring and are often associated with prior infection by influenza or respiratory syncytial virus.¹²⁶

Use of the conjugate pneumococcal vaccine has markedly decreased invasive pneumococcal infections in children, with a secondary reduction in adults.^{127,127a} This latter effect probably represents interruption of transmission by aerosolized droplets and direct physical contact, in that the conjugate vaccine is effective in blocking colonization.¹²⁸ However, widespread use of the conjugate vaccine in the United States has resulted in an increase in the number and proportion of cases of invasive pneumococcal disease due to isolates with polysaccharide capsule types that are not included in the seven-valent vaccine.¹²⁹ Consequently, a conjugate vaccine containing 13 capsular polysaccharide antigens was developed; this was approved by the U.S. Food and Drug Administration in 2012.

Clinical Manifestations

The classic presentation of pneumococcal pneumonia consists of a single rigor followed by sustained fever, cough, dyspnea, and production of rusty or mucoid sputum; gross hemoptysis is unusual. Severe pleuritic chest pain is common. The radiographic appearance of pneumococcal pneumonia is often either lobar consolidation (see Fig. 33-1 and eFig. 33-1) or patchy bronchopneumonia (eFig. 33-6). Although pneumococci can cause necrotizing pneumonia, cavitation rarely develops.¹²⁵ Small, parapneumonic effusions are frequently found and can progress to frank empyema. Neutropenia may develop in patients with overwhelming infection.

Microbiologic Diagnosis

Although Gram stain of purulent sputum that reveals numerous, characteristic "lancet-shaped" diplococci with blunted ends (commonly seen in pairs and short chains) in the absence of other predominant flora is strongly suggestive of pneumococcal pneumonia (Fig. 33-2), a good quality sputum specimen cannot always be obtained.¹³⁰ The organism is recovered from sputum culture in fewer than half of cases, and even a single dose of antibiotics can affect the yield of sputum cultures, which contributes to the discrepancy between sputum Gram stain and culture results. The frequency of positive blood cultures has fallen from 30% of hospitalized patients²⁰ to less than 10% in many contemporary series. This decrease may reflect a greater percentage of blood cultures drawn after antibiotics because of the emphasis on timely antibiotic doses in the emergency department, deemphasis on blood cultures in CAP in general, and/or a benefit of vaccination on invasive pneumococcal disease.

The rapid urinary antigen *S. pneumoniae* test offers an alternative approach to the diagnosis of pneumococcal CAP and is becoming more widely used in diagnosis and in narrowing antibiotic therapy.^{74,75,77,131} Despite satisfactory sensitivity and specificity, the urinary antigen test is complementary to culture methods, since it cannot provide information on antimicrobial susceptibility of the infecting organism.

Clinical Course

With an appropriate antibiotic, a clinical response is usually expected within 24 to 48 hours. The onset of suppurative complications, such as purulent pericarditis, meningitis, endocarditis, arthritis, and cellulitis after initiation of

Table 33-9 Agents for Specific Therapy of Selected Respiratory Pathogens

Type of Infection	Preferred Agent(s)	Alternative Agent(s)
COMMUNITY-ACQUIRED PNEUMONIA		
<i>Streptococcus pneumoniae</i>		
PCN-susceptible	Penicillin G, amoxicillin, clindamycin, doxycycline	Cephalosporin, macrolide,* (MIC < 2 g/mL) fluoroquinolone [†]
PCN-resistant	Agents identified using in vitro susceptibility tests, including cefotaxime, ceftriaxone, vancomycin, and fluoroquinolone [†]	Macrolide, if susceptible
<i>Mycoplasma</i>	Doxycycline, macrolide	Fluoroquinolone [†]
<i>Chlamydia pneumoniae</i>	Doxycycline, macrolide	Fluoroquinolone [†]
<i>Legionella</i>	Azithromycin, fluoroquinolone (including ciprofloxacin), [‡] erythromycin (± rifampin)	Doxycycline ± rifampin
<i>Haemophilus influenzae</i>	Second- or third-generation cephalosporin, clarithromycin, doxycycline, β-lactam/β-lactamase inhibitor, trimethoprim-sulfamethoxazole, azithromycin	Fluoroquinolone [†]
<i>Moraxella catarrhalis</i>	Second- or third-generation cephalosporin, trimethoprim-sulfamethoxazole, macrolide	Fluoroquinolone [†]
<i>Neisseria meningitidis</i>	Penicillin	Ceftriaxone, cefotaxime, cefuroxime, chloramphenicol, fluoroquinolone [†]
Streptococci (other than <i>S. pneumoniae</i>)	Penicillin, first-generation cephalosporin	Clindamycin (susceptibility should be confirmed), vancomycin
Anaerobes	Clindamycin, β-lactam/β-lactamase inhibitor, β-lactam plus metronidazole	Carbapenem
<i>Staphylococcus aureus</i>		
Methicillin-susceptible [‡]	Oxacillin, nafcillin, cefazolin; all ± rifampin or gentamicin [‡]	Cefuroxime, cefotaxime, ceftriaxone, fluoroquinolones, [†] clindamycin, vancomycin
Methicillin-resistant [‡]	Vancomycin [‡] ± rifampin or gentamicin	Linezolid, quinupristin-dalfopristin; trimethoprim-sulfamethoxazole, fluoroquinolones, [†] and tetracyclines may also show activity (in vitro testing required)
<i>Klebsiella pneumoniae</i> and other Enterobacteriaceae (excluding <i>Enterobacter</i> spp.)	Third-generation cephalosporin or cefepime (all ± aminoglycoside) carbapenem	Aztreonam, β-lactam/β-lactamase inhibitor, [§] fluoroquinolone [†]
HOSPITAL-ACQUIRED INFECTIONS		
<i>Enterobacter</i> spp.	Carbapenem, β-lactam/β-lactamase inhibitor, cefepime, fluoroquinolone; all + aminoglycoside in seriously ill patients	Third-generation cephalosporin + aminoglycoside
<i>Pseudomonas aeruginosa</i>	Antipseudomonal β-lactam [§] + aminoglycoside, carbapenem + aminoglycoside	Ciprofloxacin + aminoglycoside, ciprofloxacin + antipseudomonal β-lactam
<i>Acinetobacter</i>	Aminoglycoside + piperacillin or a carbapenem	Doxycycline, ampicillin-sulbactam, colistin
LESS COMMON PATHOGENS		
<i>Nocardia</i>	Trimethoprim-sulfamethoxazole	Imipenem ± amikacin, doxycycline or minocycline, sulfonamide ± minocycline or amikacin
<i>Coxiella burnetii</i> (Q fever)	Doxycycline	Fluoroquinolone
<i>Chlamydia psittaci</i> (psittacosis)	Doxycycline	Erythromycin, chloramphenicol
<i>Eikenella corrodens</i>	Penicillin	Tetracyclines, β-lactam/β-lactamase inhibitor, second- and third-generation cephalosporins, fluoroquinolones

*Azithromycin (IV or PO) is the preferred macrolide; clarithromycin (PO) or erythromycin (IV or PO) may also be used.

[†]Levofloxacin (IV or PO), gatifloxacin (IV or PO), moxifloxacin (IV or PO), or gemifloxacin (PO only) are preferred for *Streptococcus pneumoniae*. Ciprofloxacin has the best in vitro activity against *Pseudomonas aeruginosa*.

[‡]Rifampin and gentamicin should be reserved for cases of bacteremic *Staphylococcus aureus* pneumonia, empyema formation, or lung abscesses. Activity of rifampin and gentamicin requires laboratory confirmation for methicillin-resistant *S. aureus*.

[§]Ticarcillin-clavulanate and piperacillin-tazobactam are the preferred β-lactam/β-lactamase inhibitors for the treatment of nosocomial pneumonia due to Enterobacteriaceae. Ampicillin-sulbactam lacks adequate activity against many nosocomial enteric gram-negative bacilli.

^{||}Antipseudomonal β-lactams ceftazidime, cefepime, imipenem, meropenem, mezlocillin, piperacillin, or piperacillin-tazobactam.

MIC, minimum inhibitory concentration.

Modified from Bartlett JG, Dowell SF, Mandell LA, et al: Practice guidelines for the management of community-acquired pneumonia in adults: Infectious Diseases Society of America. *Clin Infect Dis* 31:347–382, 2000.

therapy is uncommon in the modern era. The exception is empyema, which appears to be increased due to serotype replacement in the vaccinated populations by serotypes more often associated with empyema.¹³² Pneumococcal pneumonia remains a cause of septic shock and ARDS.¹³³

Treatment

Antimicrobial resistance complicates treatment for *S. pneumoniae* in much of the world, including in the United States.¹³⁴ For nonmeningeal isolates of *S. pneumoniae*, the redefinition of full susceptibility as a *minimum inhibitory*

Figure 33-2 Gram stain of sputum from a patient with pneumococcal pneumonia. The predominant organisms are gram-positive lancet-shaped diplococci.

concentration (MIC) of penicillin less than or equal to 2 µg/mL and high-level resistance as MIC greater than or equal to 8 µg/mL markedly changed the incidence of penicillin resistance.¹³⁵ This redefinition was driven by discordance between the previous lower MIC breakpoints and clinical success rates. The rate of increase in the frequency of penicillin resistance may have stabilized, possibly as a consequence of the pneumococcal conjugate vaccine and a shift in the outpatient antibiotic prescription patterns away from β-lactams.¹³⁶

Penicillin resistance in *S. pneumoniae* is due to alterations in penicillin-binding proteins rather than to β-lactamase production. Unlike other β-lactams, cefotaxime, ceftriaxone, and cefepime retain activity against 75% to 95% of nonmeningeal isolates of *S. pneumoniae*.¹³⁷ *S. pneumoniae* resistance rates to other antimicrobials can be as high as 30% for trimethoprim-sulfamethoxazole (TMP-SMX), 16% for tetracyclines, 26% for macrolides, and 9% for clindamycin; these rates are higher among penicillin-resistant pneumococci.^{134,136} High-level macrolide resistance (MIC > 64 µg/mL) associated with the MLSB (macrolide, lincosamide, streptogramin B) phenotype is more common in Europe¹³⁸ and has been associated with in vitro resistance to clindamycin.¹³⁹ *S. pneumoniae* resistance to fluoroquinolones has also emerged with associated clinical treatment failures.^{113,136}

Recent exposure to an antibiotic increases the likelihood of the patient having a pneumococcal isolate resistant to that antibiotic (or class of antibiotics). Thus, it is important to avoid antibiotics that have been used in the prior 90 days when selecting a regimen for empirical treatment of a pneumococcal infection.¹¹³ Retrospective and prospective observational studies have suggested a benefit to treating severely ill patients with proven pneumococcal infections with both a β-lactam and a macrolide.^{76,140,141} Explanations that have been proposed to explain those results include nonbactericidal effects, such as inhibiting biofilm production, or an anti-inflammatory effect of the macrolide.

OTHER STREPTOCOCCI

Epidemiology

S. pyogenes (group A β-hemolytic streptococcus) can be found in the oropharynx of more than 20% of children and

a smaller percentage of adults. Carriage rates increase greatly during epidemics and in crowded conditions.^{128,142} In the United States, the incidence of pneumonia due to *S. pyogenes* was 0.15 to 0.35 per 100,000 persons per year, but may be as high as 3.6 per 100,000 in children.^{143,144} The organism is easily transferred between contacts, leading to epidemics of group A streptococcal pneumonia in military recruits, nursing homes, and other crowded settings.¹⁴² Pneumonia due to *S. pyogenes* most often manifests during the late winter and spring months, may follow an episode of influenza, measles, or varicella, and has been associated with increased age, alcohol abuse, diabetes mellitus, cancer, and HIV infection.^{143,144} *S. pyogenes* can cause necrotizing pneumonia¹⁴⁵ and is associated with pleural empyema.¹⁴⁶

Group B (i.e., *Streptococcus agalactiae*) streptococci are a major cause of neonatal sepsis and pneumonia. In adults, pneumonia accounts for approximately 15% of adult infections by group B streptococci.¹⁴⁷ Most adults with group B streptococcal pneumonia are debilitated and develop pneumonia as a consequence of aspiration.¹⁴⁷ Diabetes, cirrhosis, stroke, decubitus ulcer, and neurogenic bladder are also risk factors.¹⁴⁷

The *Streptococcus milleri* group C streptococci (which include *S. intermedius*, *S. anginosus*, and *S. constellatus*) have emerged as significant respiratory pathogens, predominantly causing empyema (eFig. 33-7 and Video 33-1) and lung abscesses as well as superinfection pneumonia in severe viral pneumonia.^{148,149} Infections with bacteria in this group share many of the features of anaerobic infections, including increased risk with periodontal disease and alcoholism. Other viridans and microaerophilic streptococci (α-hemolytic, nonpneumococcal) are rarely the sole pathogens in patients with pneumonia; they are more commonly found mixed with other facultative and anaerobic organisms in aspiration pneumonia.

Clinical Manifestations

CAP from these pathogens is clinically indistinguishable from pneumococcal pneumonia. Exudative pharyngitis may be evident and unilobar involvement is common with group A streptococcal pneumonia. Pleural effusions in group A streptococcal pneumonia are frequent, may be large, accumulate rapidly, and appear early in the course of the disease, particularly in children.¹⁴⁸ Pneumonia caused by other β-hemolytic streptococci is usually less abrupt and milder; pleural effusions are uncommon, and lung tissue necrosis is rare despite frequent bacteremia.¹⁴⁷ *S. milleri* infection is predominantly associated with empyema, with or without concomitant pneumonia.¹⁴⁸ Pneumothorax at the time of initial presentation appears to be more common with *S. milleri* than with other streptococcal empyemas.

Microbiologic Diagnosis

Because streptococci are common in the oropharynx, documentation of infection from these organisms requires isolation from a culture of blood, pleural fluid, or respiratory specimen obtained by means of an invasive procedure (Fig. 33-3). Pleural fluid cultures of children with *S. pyogenes* pneumonia are frequently positive. Polymerase chain reaction technology holds promise for aiding diagnosis, especially of group A streptococcal infections¹⁵⁰ and *S. milleri* empyema.¹⁴⁹

Figure 33-3 Streptococcus. **A**, Group A streptococcus (*Streptococcus pyogenes*, β -hemolytic streptococcus). **B**, Group B streptococcus (*Streptococcus agalactiae*) are indistinguishable from *Streptococcus pneumoniae* on Gram stain. Both form long chains containing multiple bacteria.

Clinical Course

Empyema and/or pericarditis are seen in 5% to 30% of patients with group A streptococcal pneumonia¹⁴³; other complications include pneumothorax, mediastinitis, and bronchopleural fistula formation. The only classic nonsuppurative complication that follows *S. pyogenes* pneumonia is glomerulonephritis.

Treatment

Most of these streptococci are susceptible to penicillin G, ampicillin, and many cephalosporins, although α -hemolytic streptococci may require high dosage, due to the phenomenon of tolerance (growth inhibition without killing, at low and intermediate drug concentrations). Because resistance to clindamycin and erythromycin is found in up to 15% to 20% of isolates, susceptibility testing is advisable before monotherapy with a macrolide or clindamycin.¹⁵¹ As for empyemas caused by other pathogens, drainage of empyema fluid is an important component of therapy.

HAEMOPHILUS INFLUENZAE

Epidemiology

Invasive infection, especially pneumonia, due to *H. influenzae* is estimated to account for approximately 1.2 cases per 100,000 adults per year in the United States, and is one of the more common causes of pneumonia in adults requiring

Figure 33-4 Haemophilus influenzae. Gram stain shows small pleomorphic coccobacilli diffusely across the field that, because of their size, can be missed on sputum examination.

hospitalization. Chronic lung disease, malignancy, HIV infection, and alcoholism are among the most common predisposing conditions to *Haemophilus* pneumonia. Active smoking appears to particularly increase the risk of *H. influenzae* pneumonia.

As with *S. pneumoniae*, vaccination against *H. influenzae* type b significantly changed the epidemiology of childhood pneumonia.¹⁵² Vaccinated children are still susceptible to unencapsulated (or nontypeable) strains but the incidence of *H. influenzae* pneumonia has fallen dramatically. Nonbacteremic infection by unencapsulated or non-type b strains is the most common form of *H. influenzae* pneumonia in adults.¹⁵²

Clinical Manifestations

Haemophilus pneumonia is clinically indistinguishable from other bacterial pneumonias (eFig. 33-8). On radiographs, *Haemophilus* pneumonia may be multilobar, patchy bronchopneumonia or have areas of frank consolidation. Spherical radiographic opacities (so-called round pneumonia) have been described, but cavitation is uncommon. Small parapneumonic effusions may occasionally progress to empyema. Bacteremia is more common in children than in adults.

Microbiologic Diagnosis

Diagnosing *H. influenzae* pneumonia by a Gram stain of sputum is difficult, because the small, pleomorphic coccobacilli are often overlooked. Culture of expectorated sputum reveals *H. influenzae* in only half of well-documented cases of pneumonia. Asymptomatic colonization with nontypeable strains in patients with COPD complicates analysis of Gram stain and sputum cultures (Fig. 33-4).

Clinical Course

The overall mortality rate of *H. influenzae* pneumonia is 5% to 7% but is higher in patients with bacteremia or extrapulmonary disease.¹⁵² Associated foci of infection, such as empyema, meningitis, arthritis, pericarditis, and epiglottitis are more common with encapsulated (type b) *H. influenzae*.

Treatment

H. influenzae isolates produce β -lactamase in 20% to 50% of cases and are therefore resistant to ampicillin. Increasing

macrolide resistance also compromises empirical therapy with these agents. Consequently, serious *H. influenzae* respiratory tract infections should be treated with a second- or third-generation cephalosporin, β -lactam/ β -lactamase inhibitor, or fluoroquinolone while awaiting results of susceptibility testing.

MYCOPLASMA PNEUMONIAE

Epidemiology

M. pneumoniae accounts for up to 37% of CAP in persons treated as outpatients and 10% of pneumonias requiring hospitalization.^{20,22} In the United States, there is an estimated 2 cases per year per 1000 individuals. *Mycoplasma* infections are seen throughout the year, but outbreaks are most common in the fall. Because *Mycoplasma* is readily transmitted from person to person via aerosolized respiratory droplets, outbreaks are common in families or closed populations.¹⁵³

Clinical Manifestations

The clinical picture of *M. pneumoniae* pneumonia is the paradigm of atypical CAP,^{18,21} as described previously. Pharyngitis, cervical adenopathy, and bullous myringitis may be encountered, although the latter is not more common with *Mycoplasma* pneumonia than with pneumococcal pneumonia/otitis. A wide variety of exanthems, including maculopapular eruptions, urticaria, erythema multiforme, and erythema nodosum, develop in 10% to 25% of patients. The chest radiograph usually shows an interstitial or a mixed pattern that may be more striking than expected based on chest physical findings (Fig. 33-5 and eFig. 33-9). Other chest radiographic patterns are occasionally encountered as well (eFig. 33-10).

Figure 33-5 Radiographic findings in *Mycoplasma pneumoniae* pneumonia are nonspecific. Bilateral bronchopneumonia is seen in this patient.

Microbiologic Diagnosis

When obtained, sputum generally displays moderate numbers of polymorphonuclear leukocytes without a predominant organism. Recovery of *M. pneumoniae* from culture of clinical specimens requires special media and takes approximately 10 days. Although acute *Mycoplasma* pneumonia may stimulate cold agglutinin production in a titer of 32 or greater, this nonspecific result is also found in various other infectious and noninfectious conditions including pneumonia due to *Legionella*, adenovirus, and influenza.¹⁸ The shortcomings of staining, culture, and serology for detection of *Mycoplasma pneumoniae* make this pathogen especially suitable for diagnosis by nucleic acid testing. Several nucleic acid tests for *M. pneumoniae* are currently available, and their role in management of CAP is being defined (see Chapter 17).

Clinical Course

Mycoplasma pneumonia is usually a benign, often self-limited infection with an excellent prognosis for complete recovery. ARDS and death have been reported but are rare. A unique aspect of *M. pneumoniae* infection is the frequency of associated autoimmune disorders including fulminant autoimmune hemolytic anemia, Stevens-Johnson syndrome, aseptic meningitis, meningoencephalitis, pericarditis, and myocarditis.¹⁵⁴

Treatment

Antimicrobial therapy with a tetracycline, macrolide, or fluoroquinolone shortens the course of clinical symptoms and hastens resolution of radiographic abnormalities. To prevent clinical relapse, 2 weeks is the minimum recommended duration for treatment.¹⁸ Respiratory isolation can limit transmission, and azithromycin prophylaxis can prevent infection in close contacts of patients.¹⁵⁵

CHLAMYDOPHILA PNEUMONIAE

Epidemiology

C. pneumoniae (formerly *Chlamydia pneumoniae*) accounts for 5% to 15% of cases of CAP.²² Seroepidemiologic studies suggest that *C. pneumoniae* eventually causes infection in 40% to 50% of the general population.

Clinical Manifestations

Primary infection by *C. pneumoniae* is usually asymptomatic; an acute, mild respiratory tract infection is observed in only 10% of infected adolescents and young adults.¹⁵⁶ There may be bronchitis, sinusitis, laryngitis, tonsillitis, or exacerbations of asthma, with or without associated pneumonia. Sore throat with hoarseness is often severe and may precede pneumonia by up to a week and resolve before pneumonia onset, resulting in a biphasic illness. The erythrocyte sedimentation rate is elevated, but leukocytosis or elevated PCT may be absent.

Microbiologic Diagnosis

C. pneumoniae cannot be visualized by Gram stain, and tissue culture is required to grow the pathogen. Although direct fluorescent antibody detection of *C. pneumoniae* is

available, nucleic acid testing is emerging as a rapid, sensitive mode of detection that yields results in a time frame useful for clinical management (see Chapter 17).

Clinical Course and Treatment

Complete recovery following *C. pneumoniae* infection is the rule; fatalities are principally seen in patients with mixed infection and preexisting illness.^{156,157} When associated with an exacerbation of asthma, *C. pneumoniae* can require a prolonged time for recovery. Two-week treatment with a macrolide, tetracycline, doxycycline, or fluoroquinolone is recommended.^{18,157} Older adults can be reinfectd, often with severe symptoms.

STAPHYLOCOCCUS AUREUS

Epidemiology

S. aureus accounts for less than 10% of cases of CAP,²¹ but is the second or third most common etiology in patients with CAP requiring ICU admission. *S. aureus*, especially MRSA, accounts for up to 30% of nosocomial pneumonias.²⁹ Nasal colonization is the major source for pneumonia and other invasive *S. aureus* infections: 30% to 50% of healthy adults carry the organism transiently in the anterior nares. Health care workers may have even higher carriage rates. Although the organism is easily transferred from person to person by direct hand contact, 67% of patients in whom MRSA pneumonia develops have nasal colonization on admission, indicating that most cases of *S. aureus* HAP are not due to *S. aureus* transmission in the hospital.¹⁵⁸

A community-acquired strain of MRSA (CA-MRSA) has become an important CAP pathogen.¹⁵⁹⁻¹⁶² In addition to antibiotic resistance, the DNA cassette containing the *mecA* gene that confers methicillin resistance to this strain includes other virulence factors. The combination of antibiotic resistance and multiple virulence factors is associated with significantly higher mortality.¹⁶³ Typical hospital-acquired strains of MRSA also cause CAP but usually in patients with risk factors for HCAP.¹⁶⁴ The ability to differentiate clinically between hospital- and community-acquired cases is increasingly difficult because risk factors, such as prior antibiotic therapy, often overlap.

Factors that predispose patients to acquire staphylococcal pneumonia include underlying pulmonary disease (e.g., COPD, carcinoma, cystic fibrosis), chronic illness (e.g., diabetes mellitus, renal failure), or viral infection (e.g., influenza, measles).¹⁶⁵ *S. aureus*, including CA-MRSA, is second in frequency to *S. pneumoniae* as a cause of postinfluenza bacterial pneumonia. Postinfluenza CAP due to CA-MRSA is associated with a high frequency of complications and mortality. Pneumonia due to hematogenous spread of *S. aureus* is a unique type of pneumonia, usually a consequence of intravenous drug use or septic embolization from endocarditis or an infected vascular site.

Clinical Manifestations

CA-MRSA pneumonia can be seen in young patients without underlying illnesses. The clinical presentation in severe cases includes high fever, hypotension, and

hemoptysis with rapidly progressive deterioration and septic shock. Leukopenia, rather than leukocytosis, is observed in a substantial fraction of cases and is associated with poor outcomes.^{159,161,165} The radiographic features of CA-MRSA pneumonia include multilobar opacities and/or cavitory lesions (eFig. 33-11).

In cases acquired hematogenously such as in endocarditis or other endovascular infection, signs and symptoms related to the underlying endovascular infection predominate; if pulmonary infarction results from a septic embolism, pleuritic chest pain and hemoptysis are often noted. Otherwise, respiratory tract symptoms are mild or absent. The chest radiograph in patients with hematogenous staphylococcal pneumonia often reveals multiple, discrete, and often cavitory shadows with a predilection for the lower lobes (Fig. 33-6).¹⁶⁶

Microbiologic Diagnosis

Purulent sputum with multiple clusters of large gram-positive cocci, particularly if intracellular, is strongly suggestive of *S. aureus* pneumonia (Fig. 33-7). The organism is easily recovered from sputum cultures. Absence of MRSA on culture, even after several doses of antibiotics, is strong evidence that MRSA is not the causative pathogen. Fewer than 15% of pneumonias due to aspiration are associated with positive blood cultures. In contrast, hematogenous staphylococcal pneumonia usually yields multiple positive blood cultures. CA-MRSA pleural effusions are often exudative rather than grossly purulent but are still high yield on culture. An important clue to CA-MRSA is the presence of skin lesions,¹⁶⁷ which are often positive on Gram stain as well.

Figure 33-6 Chest radiograph shows hematogenous staphylococcal pneumonia associated with bacterial endocarditis. The pneumonia is characterized by many cavities.

Figure 33-7 Staphylococcus. Gram stain of sputum from a patient with staphylococcal pneumonia shows abundant large, round gram-positive cocci in clusters.

Clinical Course

Even with appropriate antibiotics, the duration of fever and need for ICU care is often prolonged for *S. aureus* pneumonia, particularly CA-MRSA. Local complications of staphylococcal pneumonia include empyema and abscess formation. Infection can spread hematogenously to the central nervous system, bones, joints, skin, and kidneys. Cavities and necrotic tissue may prevent adequate local antibiotic penetration, whereas unrecognized or incompletely drained empyema may prolong fever. Most of these manifestations are due to strains secreting Panton-Valentine leukocidin or one of the other exotoxins produced by *S. aureus*. Pleuroscopy or decortication is required in a large percentage of cases with empyema.

The mortality of *S. aureus* CAP is generally higher than most etiologies, with the mortality in methicillin-sensitive strains about 30%. *S. aureus* CAP following influenza has a reported mortality of greater than 60%, even if not methicillin-resistant.¹⁶

Treatment

The treatment of choice for methicillin-susceptible *S. aureus* pneumonia is a penicillinase-resistant penicillin (e.g., oxacillin 8 to 12 g/day) or a first-generation cephalosporin. Therapy for 7 to 10 days is adequate in uncomplicated cases, but 4 to 6 weeks of treatment is recommended for patients with bacteremia or cavitation. In the penicillin-allergic patient, clindamycin or linezolid can be used.

Treatment of MRSA pneumonia is more challenging, and the incidence of CAP caused by both health care-associated MRSA and CA-MRSA strains is increasing. Although resistance to vancomycin is still rare, the MIC has been shifting upward and MICs greater than 1 µg/mL have been associated with clinical failure. In higher-risk patients, such as those with VAP or with underlying renal insufficiency, linezolid has been found to have better clinical response rates than vancomycin, although differences in patient survival have been variable.¹⁶⁸⁻¹⁷⁰ For CA-MRSA, vancomycin therapy alone has been associated with a significant failure rate.^{160,163} Addition of clindamycin or use of linezolid has been associated with improved outcomes in small case series. Unlike in MRSA skin infections, clindamycin, fluoroquinolones, and TMP-SMX are unreliable in severe CA-MRSA cases. Daptomycin is ineffective for

treatment of pneumonia, because it binds to and is inactivated by pulmonary surfactant.¹⁷¹

GRAM-NEGATIVE BACILLARY PNEUMONIA

The term *gram-negative bacillary pneumonia* refers to infections caused by members of two groups, the Enterobacteriaceae and Pseudomonadaceae and other aerobic gram-negative bacilli. Infections caused by *Haemophilus*, *Legionella*, and anaerobes are usually excluded from this categorization.

Enterobacteriaceae

Epidemiology. While they are more common as causes of HAP, gram-negative bacilli may cause up to 5% to 10% of CAP.^{21,24,111} CAP due to gram-negative bacilli is often severe and frequently requires ICU care. Patients in an ICU, especially those undergoing mechanical ventilation, have the highest risk for development of gram-negative bacillary pneumonia.

The Enterobacteriaceae normally colonize the digestive tract, and pneumonia usually results from aspiration of oropharyngeal flora. Although uncommon in healthy, non-hospitalized individuals, oropharyngeal colonization by gram-negative bacilli is greatly increased by hospitalization and antimicrobial use; the risk for aspiration is increased by comorbidities, such as cerebrovascular accidents, seizures, or anesthesia.²⁴ Occasionally, contaminated home respiratory therapy equipment directly introduces gram-negative rods into the respiratory tract. Finally, Enterobacteriaceae pneumonia may result from hematogenous seeding from infection at other anatomic sites.

Among the Enterobacteriaceae, *Escherichia coli* is the single most frequent cause of CAP.²⁴ The classic cause of community-acquired gram-negative bacillary pneumonia, *K. pneumoniae* (Friedlander pneumonia), causes fewer than 10% of CAPs, but more than 20% of nosocomial pneumonias. Alcohol abuse is the most common underlying condition for community-acquired *K. pneumoniae* pneumonia. Other underlying conditions that predispose to *Klebsiella* infections are diabetes mellitus and COPD.

Clinical Manifestations. In *Klebsiella* CAP, a syndrome of pleuritic chest pain, hemoptysis, and bloody sputum (occasionally with a “currant jelly” appearance) is classic but rarely seen. The clinical manifestations of Enterobacteriaceae pneumonias are not sufficiently unique to distinguish these infections from pneumonias due to other causes.²⁴

Most laboratory abnormalities are nonspecific, but neutropenia is associated with a poor prognosis. Chest radiographs often demonstrate lower lobe bronchopneumonia (eFig. 33-12), which is often bilateral. A classic radiographic appearance of *Klebsiella* pneumonia is upper lobe consolidation (especially on the right) (Fig. 33-8) with a bulging or bowed fissure. This manifestation is now uncommon. *Klebsiella* can also cause lung abscess (eFig. 33-13) in patients with HCAP.

Microbiologic Diagnosis. Enterobacteriaceae pneumonia should be suspected when sputum Gram stain reveals large numbers of uniform-appearing gram-negative rods

Figure 33-8 *Klebsiella pneumoniae* lobar pneumonia with “bulging” fissure. Frontal chest radiograph shows dense right upper lobe air-space opacity, which bows the right minor fissure inferiorly (arrows). The bulging fissure sign at chest radiography is traditionally associated with *Klebsiella pneumoniae* infection, but is actually nonspecific, and can be seen with other pulmonary infectious and noninfectious pulmonary processes as well. (Courtesy Michael Gotway, MD.)

Figure 33-9 *Klebsiella pneumoniae*. Large gram-negative rods in the sputum of a patient with *Klebsiella pneumoniae* pneumonia (arrows).

(Fig. 33-9). Sputum culture alone is nonspecific for Enterobacteriaceae in either nonintubated or intubated patients because of oropharyngeal colonization and is one of the major reasons for interest in quantitative cultures as an approach to distinguishing colonization from infection.

Clinical Course. Enterobacteriaceae pneumonia fatality rates are 25% to 50%.²⁴ Bacteremia, neutropenia, and advanced age contribute to a poor prognosis. Destruction of pulmonary alveolar septae may lead to cavitation.

Treatment. Treatment of serious infections due to Enterobacteriaceae is complicated by widespread antimicrobial resistance. Extended-spectrum β -lactamase, carbapenemase, fluoroquinolone, and aminoglycoside resistance are all common in patients infected with Enterobacteriaceae.^{172,173} Due to regional and institutional variations in the frequency of resistance to specific drugs and classes of

drugs, initial therapy of possible Enterobacteriaceae pneumonia must be selected using knowledge of local antibiotic resistance patterns. In patients with serious infection, a two-drug regimen of an aminoglycoside with a broad-spectrum β -lactam or carbapenem is recommended for treatment until susceptibility results are known. Monotherapy may be reasonable for immunocompetent patients with mild to moderate disease who are infected with susceptible strains of *Proteus*, *Morganella*, *K. pneumoniae*, or *E. coli*. Recommendations for empirical therapy for HAP are listed in Table 33-8, although local resistance patterns must be taken into account.

***Pseudomonas aeruginosa* and Related Organisms**

Epidemiology. *P. aeruginosa* is an uncommon cause of CAP except in specific risk groups. Although one large study in Spain found that 7% of CAP was due to *P. aeruginosa*, most studies have found substantially lower rates.^{24,111} One major risk factor for *Pseudomonas* CAP is structural lung disease, such as cystic fibrosis, bronchiectasis, and severe COPD (forced expiratory volume in 1 second <30%). Another risk factor is HIV infection, especially with a marked deficiency of CD4⁺ T cells.¹⁷⁴⁻¹⁷⁶ *Pseudomonas* pneumonia in AIDS patients can be severe, with mortality rates as high as 50%, and be associated with cavitation, even when the patient has a profound CD4⁺ T-cell deficiency. The incidence of *Pseudomonas* pneumonia has decreased with widespread availability of combination antiretroviral therapy. *Pseudomonas* pneumonia is rare in normal hosts, but it can develop after exposure to aerosols of contaminated water such as in hot tubs.^{21,24,40,68,177,178}

P. aeruginosa is a leading cause of nosocomial pneumonia and a particularly frequent cause of VAP.¹⁷⁹ Prolonged endotracheal intubation and prior antibiotic therapy, especially with broad-spectrum antibiotics, are major risk factors for *Pseudomonas* VAP. Other nonfermenters, such as *S. maltophilia* and *B. cepacia*, cause pneumonia in patients after prolonged broad-spectrum antibiotic therapy, and are associated with a high mortality rate. *B. cepacia* is also found in outpatients with cystic fibrosis.

Clinical Manifestations. The clinical picture of pneumonia due to *P. aeruginosa* (eFig. 33-14) is indistinguishable from that of the Enterobacteriaceae. Bacteremia is slightly more common than for other gram-negative pathogens; physical examination may reveal ecthyma gangrenosum, and leukopenia is common. Its propensity to invade vascular tissue makes *Pseudomonas* the most common cause of cavitary pneumonia (eFigs. 33-15 and 33-16) in hospitalized or immunocompromised patients, and empyema can develop.

Microbiologic Diagnosis. Gram-stained sputum from patients with *Pseudomonas* pneumonia typically shows many slender, gram-negative bacilli (Fig. 33-10); neutrophils are commonly abundant in the sputum except in neutropenic patients. Since *Pseudomonas* and other gram-negative bacilli colonize the oropharynx in hospitalized or debilitated patients, Gram stain results in these patients can be misleading. In endotracheally intubated patients, the absence of *Pseudomonas* on culture is strong evidence against *Pseudomonas* as the cause of the patient's pneumonia, because the organism is typically easy to recover.

Figure 33-10 *Pseudomonas*. Gram stain of sputum showing slender gram-negative bacilli (arrows).

Clinical Course. Mortality from community-acquired *P. aeruginosa* pneumonia can exceed 25%,²⁴ and in persons with VAP due to *P. aeruginosa*, mortality rates are 40% to 70%. The prognosis in neutropenic patients with *P. aeruginosa* pneumonia is particularly poor.¹⁸⁰ *P. aeruginosa* VAP can recur in 25% to 50% of cases, approximately half due to a new strain.

Treatment. *P. aeruginosa* pneumonia should initially be treated with two antimicrobial agents expected to be active against isolates in the region, such as an aminoglycoside and an antipseudomonal β -lactam antibiotic; this is especially true for bacteremic or neutropenic patients.¹⁸⁰ Amikacin is the most reliably active aminoglycoside in most regions. The β -lactam antibiotics, in descending order of probable activity against *P. aeruginosa*, are the carbapenems (imipenem and meropenem), the acylureidopenicillins (e.g., piperacillin), cefepime, and ceftazidime.¹⁸¹ Although fluoroquinolones (particularly ciprofloxacin) initially possessed good intrinsic activity against *P. aeruginosa*, resistance is now common, making empirical fluoroquinolone monotherapy hazardous. Resistance can emerge in *Pseudomonas* during the course of fluoroquinolone monotherapy.

S. maltophilia is inherently resistant to most standard antibiotics.¹⁸² TMP-SMX is the most reliable agent, while fluoroquinolones or ticarcillin-clavulanate have activity against some strains.¹⁸⁰ Isolates of *S. maltophilia* may become resistant in the face of seemingly effective therapy. *B. cepacia* may be susceptible to acylureidopenicillins, ceftazidime, TMP-SMX, fluoroquinolones, minocycline, and chloramphenicol. Resistance rates are higher in isolates from patients with cystic fibrosis.

Acinetobacter baumannii

Epidemiology. *A. baumannii* may cause either CAP or HAP/VAP. *Acinetobacter* causes CAP in hot climates, both dry¹⁸³ and humid,^{45,184} and has become one of the most common causes of CAP in southeast Asia. In the United States, *Acinetobacter* CAP is most commonly seen in male alcoholics. The risk of *Acinetobacter* VAP varies widely by region and by health care facility. Nosocomial infections caused by *Acinetobacter* show seasonal variation, peaking in late summer, similar to patterns in CAP.

Clinical Manifestations. Patients with *Acinetobacter* CAP often present acutely ill and may have leukopenia, pleural

effusions, and empyema.¹⁸⁵ Nosocomial *Acinetobacter* pneumonia has a less dramatic presentation, similar to those of other hospital-acquired gram-negative pneumonias.⁴⁵

Microbiologic Diagnosis. Examination of expectorated sputum, which is usually purulent, may reveal a predominance of paired gram-negative coccobacilli that resemble *Neisseria*, *Haemophilus*, and *Moraxella* species. Bacteremia complicates community-acquired more often than nosocomial *Acinetobacter* pneumonia.

Clinical Course. The mortality rate of community-acquired *Acinetobacter* pneumonia approaches 50%.⁴⁵ Patients at greatest risk of death are those with leukopenia or empyema. The fatality rate for nosocomial *Acinetobacter* pneumonia is determined by the severity of underlying disease.

Treatment. Community isolates of *A. baumannii* can be susceptible to amikacin, tobramycin, ceftazidime, carbapenems, and doxycycline.¹⁸⁶ Nosocomial *Acinetobacter* species are resistant to most β -lactams and aminoglycosides and therefore are most reliably treated with carbapenems, but poor outcomes are common.¹⁸⁷ Some investigators have reported successful treatment of highly resistant isolates with ampicillin-sulbactam or colistin.^{188,189} Resistance to β -lactam antimicrobials, carbapenems, aminoglycosides, fluoroquinolones, and even polymyxin B and colistin¹⁸⁹ is increasingly common among nosocomial isolates.

LEGIONELLA

Epidemiology

L. pneumophila causes both epidemic and sporadic infections; both patterns may be seen either in the community or in hospitals. Outbreaks have been linked to contaminated potable water systems, ultrasonic mist devices, whirlpool baths, air-conditioning condensates, and water-evaporative systems.¹⁹⁰

Legionella is acquired through inhalation of contaminated aerosols or aspiration. Sporadic cases of *L. pneumophila* pneumonia (50% to 80% of which are due to serogroup 1) account for 2% to 6% of CAPs in immunocompetent hosts.²¹ *L. pneumophila* is one of the most common causes of severe CAP in certain communities. Risk factors include exposure to contaminated water, immunosuppression, cigarette use, diabetes, cancer, end-stage renal disease, and alcohol use. Infection with *L. pneumophila* is more common in specific geographic regions, such as the Mediterranean or the northeastern United States.

In addition to *L. pneumophila*, 40 other *Legionella* species have been identified. Many, such as *Legionella micdadei* and *Legionella longbeachae*, produce a pneumonic illness indistinguishable from that of *L. pneumophila*. Much less is known about the epidemiology of non-pneumophila *Legionella* infections, but they also appear to be from water or soil-related sources. Immunosuppression appears to be the major host risk for these species.

Clinical Manifestations

The incubation period for *Legionella* pneumonia is 2 to 10 days. Lethargy, headache, fever, recurring rigors, anorexia,

and myalgias are frequent early symptoms. After several days, cough becomes more pronounced; occasionally, watery or purulent sputum develops. Dyspnea is prominent in half of cases, and one third of patients complain of pleuritic chest pain. Extrapulmonary manifestations may overshadow respiratory complaints; gastrointestinal (watery diarrhea, nausea, vomiting, abdominal pain) and neurologic symptoms and signs (headache, confusion, obtundation, seizures, hallucinations) are particularly noteworthy. Patients may appear acutely ill. Temperatures reach 40.5° C in one third of patients, are typically sustained, and may be accompanied by relative bradycardia. Physical findings are usually limited to the chest, including pleural friction rubs, but generalized abdominal tenderness, hepatomegaly, splenomegaly, cutaneous rash, nuchal rigidity, and focal neurologic deficits have all been described.

Hyponatremia and hypophosphatemia are present in more than half of severe cases. Mild elevations of serum creatinine, creatine phosphokinase, and liver enzymes are also common, as are hematuria and proteinuria and occasionally frank rhabdomyolysis. There may be leukopenia and thrombocytopenia especially in severely ill patients. Cold agglutinins may be present, as in infection due to *M. pneumoniae*.

Chest radiographic findings typically lag behind the early clinical illness (Fig. 33-11). Small pleural effusions develop in 50% and may precede the parenchymal process. Multilobar opacities are commonly seen (eFig. 33-17), particularly on chest CT. Frank cavitation rarely is seen.⁶⁶

Microbiologic Diagnosis

Legionella are obligatory aerobic, fastidious, gram-negative bacilli that stain poorly with Gram stain (see Chapter 17,

Figure 17-4) and grow poorly on conventional media. *L. micdadei* and some other *Legionella* species may stain weakly acid-fast. Early in the infection, sputum Gram stain from patients with *Legionella* pneumonia contains few or no polymorphonuclear leukocytes. The sensitivity of cultures of respiratory specimens is as low as 10%, despite use of appropriate media. Culture diagnosis of *L. pneumophila* infection often requires invasive procedures because at least 25% of patients with *Legionella* infection do not produce sputum.⁷⁶ Rarely, *Legionella* has been recovered from blood, pleural fluid, and other extrapulmonary sites.

The *Legionella* urinary antigen test is currently the most commonly used method of diagnosis. It has a sensitivity of 60% to 80% and specificity greater than 95% for *L. pneumophila* serogroup 1, but the test is limited to this single species and serogroup.⁷⁶ The sensitivity of direct fluorescent antibody assay for sputum ranges from 33% to 68%, with specificity greater than 95%,⁷⁶ but its use is hindered by difficulty of obtaining sputum in some patients, the expertise required for interpretation, and the requirement for specific antibodies to the multiplicity of *Legionella* species and serogroups. Polymerase chain reaction–based assays for sputum have greater than 80% sensitivity and greater than 90% specificity, and their availability is likely to become more widespread.⁷⁶

Clinical Course

A clinical response to appropriate antibiotic therapy is usually observed within the first 48 hours. In contrast, radiographic findings may temporarily continue to progress despite observed clinical improvement and ultimately take months to resolve.⁶⁶ Acute renal failure and oliguria, often independent of shock and myoglobinuria, may develop in

Figure 33-11 *Legionella pneumophila* pneumonia: unilateral disease. A, Frontal chest radiograph shows subpleural left upper lobe consolidation (arrows). B–E, Axial chest CT displayed in soft tissue (B and C) and lung (D and E) windows confirms left upper lobe consolidation (arrows). A small left pleural effusion (*) is present. (Courtesy Michael Gotway, MD.)

approximately 10% of patients and dialysis may be required. Many patients note lingering fatigue and weakness for months following *Legionella* pneumonia.

The mortality of community-acquired *Legionella* pneumonia is approximately 15%. Poor clinical outcomes are associated with immunodeficiencies, comorbidities, delayed initiation of appropriate therapy, and the need for ventilatory support or dialysis.

Treatment

Azithromycin and fluoroquinolones are superior to erythromycin or clarithromycin for treatment of *Legionella* infections. Although never used alone, the addition of rifampin is advised for patients who are severely ill or immunocompromised.¹⁸ Antibiotics should be continued for 10 to 21 days in immunocompetent patients to decrease the rate of relapse.¹⁸

ANAEROBIC BACTERIA

Epidemiology

Mixed aerobic and anaerobic infection is usually a complication of macroaspiration of oropharyngeal contents. Rare causes include rupture of the esophagus and extension of intra-abdominal abscesses. Underlying pulmonary conditions such as malignancy and pulmonary infarction are present in 20% of patients who have an anaerobic lung infection. Although acute complications of macroaspiration are largely due to a chemical injury pneumonitis (Mendelson syndrome) and/or infection by pathogenic aerobes in the oral flora, many of these episodes later result in the emergence of mixed aerobic and anaerobic pneumonia.

Clinical Manifestations

Anaerobic infections present as four different syndromes: chemical pneumonitis, aspiration pneumonia, anaerobic pleuropneumonia, or primary anaerobic empyema.

Chemical pneumonitis can precede anaerobic pneumonia, and is characterized by the acute onset of hypoxemia, fever, cough (often dry), dyspnea, and pleuritic pain. The foul sputum and hemoptysis characteristic of anaerobic lung abscess are absent at this stage. The risk of infection is dependent on the nature of the inoculum; many cases of aspiration pneumonitis are inflammatory alone and not infectious. Imaging may demonstrate bronchopneumonic opacities, but usually not lobar consolidation, in the aspiration-prone segments of the lung (e.g., posterior segment of the right upper lobe and superior segment of the right lower lobe; see eFig. 33-3). ARDS is a common complication of aspiration of low pH gastric fluid.

Aspiration pneumonia is indistinguishable from either CAP or HAP (eFig. 33-18), with the exception that it is seen in patients with risk factors for macroaspiration. Rapid development of pulmonary opacities over a short period of time may suggest the diagnosis of aspiration pneumonia (Fig. 33-12 and eFig. 33-19). High concentrations of amylase or pepsinogen in BAL fluid are very suggestive of this entity.¹⁹¹ Localization of an opacity in a dependent lung segment has less discriminating value.

Anaerobic pleuropneumonia is characterized by necrosis and suppuration of lung parenchyma. Early in the course,

Figure 33-12 Aspiration pneumonitis: rapid interval development of pulmonary opacities. **A**, Frontal chest radiograph performed for central venous catheter placement shows a right subclavian central venous catheter without pneumothorax; the lungs are clear. **B**, Repeat frontal chest radiograph obtained following an episode of altered level of consciousness and vomiting only a few hours after **A** shows interval development of extensive mid and lower lung consolidation. Such rapid development of extensive pulmonary opacities in the context of mental status changes accompanied by vomiting is characteristic of aspiration. The differential diagnosis of rapid interval appearance of extensive pulmonary opacities also includes increased pressure edema, noncardiac edema injury, and hemorrhage. (Courtesy Michael Gotway, MD.)

imaging may demonstrate dense segmental opacification with multiple small lucent areas of lung necrosis (<2 cm in diameter), usually without air-fluid levels (eFig. 33-20). In the absence of appropriate treatment, these lesions may evolve into a primary lung abscess (eFig. 33-21) and empyema. Patients commonly present with fatigue, low-grade fever, weight loss, and productive cough for several weeks after an episode of loss of consciousness. Approximately half describe putrid sputum, and some may have hemoptysis. Patients appear chronically ill and toxic, with temperatures up to 39° C. In some patients, a single lung abscess greater than 2 cm in diameter is detected in a dependent lung segment on radiography (Fig. 33-13). The abscess may be multilocular; occasionally, multiple abscesses are located in different lung segments.

Figure 33-13 A single parenchymal cavity with an air-fluid level typifies an anaerobic lung abscess. Most often, these lesions are located in the dependent, aspiration-prone lung segments (superior segment of the right lower lobe and left lower lobe and posterior segments of the upper lobes). This patient also has a small left empyema.

Primary anaerobic empyemas are usually due to *S. milleri/intermedius* (see eFig. 33-7) rather than anaerobes.¹⁴⁹ However, anaerobes still play a significant role. In these cases, the pleural manifestations may dominate, with less evidence of pneumonia. Anaerobic empyema can also be seen in the absence of parenchymal lung infection when empyema develops in association with esophageal rupture or from subphrenic or other intra-abdominal abscesses. More information on pleural empyema is in Chapter 80.

Microbiologic Diagnosis

Gram stain of sputum or examination of a bronchoscopically obtained specimen from a patient with anaerobic pneumonia reveals numerous polymorphonuclear leukocytes with an abundance of intracellular and extracellular bacteria. Typically, a mixture of Gram stain reactions and morphologies are seen, including pale-staining gram-negative rods with tapered ends (suggestive of *Fusobacterium nucleatum*), small, pale-staining gram-negative coccobacilli, and chains of tiny gram-positive cocci.

Because the endogenous flora of the upper respiratory tract predominantly consists of anaerobic bacteria, cultures of expectorated sputum are not appropriate for diagnosis of anaerobic infections. With careful technique, recovery on average of 3.2 bacterial isolates, of which 80% are anaerobes, is possible in a case of mixed aerobic/anaerobic pneumonia or empyema. The most common anaerobes in pleuropulmonary infections include *E. nucleatum*, *Prevotella*, *Porphyromonas*, *Peptostreptococcus*, and microaerophilic *Streptococcus*. The major aerobic and facultative organisms recovered in conjunction with anaerobes are *Streptococcus* species. Although *S. aureus*, various enteric gram-negative bacilli, and *Pseudomonas* may also be isolated, their significance is often questionable. Molecular techniques can often identify anaerobes in culture negative cases.¹⁴⁹

Clinical Course

Uncomplicated aspiration pneumonia generally responds promptly to appropriate antibiotics. Fever resolves within a few days, and the chest radiograph normalizes within 3 weeks. Fever resolves more slowly in anaerobic pleuropulmonary infection. Closure of abscess cavities (see eFig. 33-21) and resorption of empyema collections may require months. Fatality rates are low in adequately treated patients, except those with necrotizing pneumonia, in which mortality approaches 20%.¹⁴⁹ Chronic lung abscess has been complicated by brain abscess, other metastatic abscess, secondary amyloidosis, life-threatening hemoptysis, bronchopleural fistula or *empyema necessitans* (rupture through the chest wall), but these complications are currently rare.

Treatment

Emergence of β -lactamase-mediated resistance mandates that penicillin G and ampicillin are no longer the drugs of choice for treatment of patients with serious anaerobic pleuropulmonary infection. There is resistance not only among *Bacteroides* species but also among *Prevotella* and some *E. nucleatum* strains. Empirical treatment for serious anaerobic pleuropulmonary infection requires the use of a β -lactam/ β -lactamase inhibitor (e.g., ampicillin-sulbactam, ticarcillin-clavulanate, or piperacillin-tazobactam) or clindamycin. Because of the frequent simultaneous presence of aerobes, metronidazole monotherapy is not adequate for suspected anaerobic pneumonia. Occasional pulmonary isolates are resistant to one or more of these agents. For example, *Eikenella corrodens* is resistant to clindamycin. Carbapenem monotherapy is also effective but generally provides unnecessarily broad coverage.

Ten days of total treatment is usually adequate for uncomplicated pneumonitis. Necrotizing pneumonia, abscess, and empyema require prolonged parenteral therapy to achieve clinical improvement, and extended courses of oral therapy, often requiring several months, may be required for cure.

Drainage of empyema fluid is required. Surgical resection of anaerobic lung abscess is almost never indicated. Bronchoscopy is useful for excluding an underlying malignancy in patients without other risk factors (i.e., edentulous patients).

NONRESPONDING PNEUMONIA/TREATMENT FAILURE

Two different clinical patterns of treatment failure in pneumonia have been described²¹²: progressive pneumonia with clinical deterioration including respiratory failure or septic shock; and nonresponding pneumonia, in which clinical improvement is not achieved (fever and clinical symptoms persist). In those treated as outpatients or inpatients, evaluation for response should be undertaken after 72 hours of antibiotic treatment, as this represents the median time required to achieve clinical improvement.²¹² In addition to clinical evaluation, reduction of procalcitonin (PCT) levels after 3 to 4 days of treatment correlates with clinical responses.²¹³ Levels of certain biomarkers, mainly PCT and

LESS COMMON CAUSES OF PNEUMONIA

A variety of pathogens are less common causes of pneumonia. These agents may be suspected in the presence of unique risk factors or presentations, or may be diagnosed by results of cultures.

ACTINOMYCOSIS

A variety of species within the two genera of the Actinomycetaceae family (*Actinomyces* and *Propionibacterium*), which are normally harmless commensals in the oropharynx, can cause subacute to chronic pulmonary infections that are virtually indistinguishable. Pulmonary actinomycosis follows aspiration of oropharyngeal material. Periodontitis and other dental disease increase the risk of cervicofacial invasion and of pneumonia. Most patients are 30 to 60 years old; men outnumber women by a ratio of 4:1.

Patients with actinomycosis appear chronically ill but not toxic. Constitutional symptoms, including fatigue, weight loss, and low-grade fever, may be present for weeks to months before diagnosis and often mimic the presentation of chronic fungal infection, tuberculosis, or malignancy. Fever may be absent. Most patients gradually develop productive cough and pleuritic chest pain, but hemoptysis and putrid sputum are unusual. Cervicofacial involvement is rarely observed in patients with thoracic involvement.

The imaging finding classic for actinomycosis is direct extension of a cavity or mass through an interlobar fissure. More commonly, changes are confined to a single lobe with one or more small cavitory lesions (eFig. 33-22). In advanced cases, the findings may be more distinctive, with penetration through the chest wall and/or destruction of adjacent bone tissue (eFig. 33-23).

Members of the *Actinomyces* and *Propionibacterium* genera are gram-positive, diphtheroidal or filamentous, branching bacilli. Most strains grow best in anaerobic conditions, although some also grow aerobically. In patients with a cutaneous chest wall sinus, the best means of establishing a diagnosis of actinomycosis is by detection of “sulfur granules” that, when crushed and stained, form a characteristic pattern of gram-positive, branching filaments (eFig. 33-24). The organism usually can be recovered from culture of this material, provided anaerobic conditions are maintained for the specimen. Diagnosis of an actinomycotic parenchymal lesion is more difficult. Sulfur granules are rarely present in sputum, and recovery of the organism in sputum cultures is unreliable because the organism may colonize without invading any mucosal surface. Definitive diagnosis depends on demonstrating the characteristic histopathology and culture from a sterile body fluid or tissue biopsy. Other organisms are commonly identified, including *Haemophilus* (*Actinobacillus*) *actinomycetemcomitans* and *Prevotella*, in addition to the *Actinomyces* or *Propionibacterium*.

Complications of pulmonary actinomycosis relate to its ability to invade across anatomic barriers. Pleural empyema, cutaneous thoracic sinuses, mediastinitis, pericarditis, and vertebral osteomyelitis are not infrequent. Metastatic infection, including brain, skin, and bone, is more commonly

seen with pulmonary actinomycosis than with other variants (e.g., cervicofacial disease) but is still unusual. With adequate therapy, death from actinomycosis is rare.

Prolonged antibiotic treatment is the key to curing actinomycosis. *Actinomyces* are universally susceptible to penicillin G, which should be given in intravenous doses of 12 to 20 million units daily for 4 to 6 weeks, followed by at least 6 months of oral penicillin V or ampicillin. Multiple other drugs have also been successfully used; prolonged therapy is essential. With polymicrobial infection, the presence of the other organisms may require modification of therapy. If β -lactamase-producing anaerobes are present, treatment choices as described for anaerobic pneumonia are recommended. On occasion, clindamycin fails because of concomitant infection by *H. actinomycetemcomitans*. Rarely, surgical resection is required for cure.

CHLAMYDOPHILA PSITTACI (FORMERLY CHLAMYDIA PSITTACI)—PSITTACOSIS

Exposure to birds is the classic risk factor for psittacosis. Multiple species harbor the organism, but most cases have been acquired from canaries, parakeets, cockatiels, parrots, and pigeons. Although infected birds are typically ill, there can be asymptomatic fecal carriage. *C. psittaci* can be detected in blood, tissues, feathers, and feces of infected birds. Human acquisition is typically via inhalation of contaminated bird excreta. Although approximately 50% of cases are reported in owners of infected pet birds, there may be sporadic cases and occasional outbreaks without a history of known bird exposure. History of exposure is more likely with more severe disease.¹⁹²

The symptoms of psittacosis may develop abruptly, with high fever and chills, or they may evolve slowly. Headache, arthralgia, and painful myalgia (especially in the head and neck) are prominent features. A severe cough develops that may be either dry and hacking or productive of mucoid sputum. Chest pain and dyspnea are present with extensive pulmonary involvement. Temperatures are 38° C to 40° C and are frequently accompanied by relative bradycardia. Splenomegaly or occasionally a pale macular rash (Horder spots) can be seen. Hematologic and blood chemistry findings are nonspecific, except occasionally for findings consistent with granulomatous hepatitis.

C. psittaci is an obligate intracellular parasite that does not stain by the Gram method but can be seen as large intracytoplasmic inclusions in infected cells when stained with Giemsa stain. Cultivation of the organism, which requires tissue culture, poses a threat to laboratory personnel and should be performed only in specialized facilities. Nucleic acid testing offers a rapid alternative method for diagnosis, with higher sensitivity than cultures.¹⁹³ In the absence of available nucleic acid testing, diagnosis of psittacosis can be made by demonstrating a fourfold rise in complement-fixing antibodies in paired acute and convalescent serum. A single titer of 16 or greater can be considered presumptive evidence of infection in a patient with a compatible illness. The antibody can cross-react with *C. burnetii* or *Brucella*.

Treatment with doxycycline is recommended, but the clinical response may be slow. Because of the risk of relapse, therapy should be given for a minimum of 2 weeks after

fever has resolved. Chloramphenicol, erythromycin, azithromycin, and moxifloxacin also have in vitro activity, but clinical experience with use of these drugs to treat *C. psittaci* is limited. The case-fatality rate is about 1% with antimicrobial therapy. Unusual complications include respiratory failure, encephalitis, hepatitis, disseminated intravascular coagulation, renal failure, and endocarditis.

COXIELLA BURNETII—Q FEVER

Worldwide, Q fever is a particular problem in farming communities in Europe, North America, and Australia. *C. burnetii* asymptomatically infects a wide variety of domestic and wild animals, as well as ticks. Transmission to humans is primarily via exposure to the urine, feces, placenta, or unpasteurized milk of an infected animal: cows, sheep, and goats are most common. Outbreaks have happened in tanneries, dairies, and wool-rendering plants, among laboratory personnel, and in household members exposed to an infected cat or dog during parturition.^{194,195}

Following an incubation period of 2 to 4 weeks, an atypical pneumonia syndrome develops in 10% to 20% of infected persons.¹⁹⁴ High temperature (>40°C), relative bradycardia, conjunctivitis, hepatosplenomegaly, and chest crackles may be detected; a rash is typically absent.¹⁹⁵

C. burnetii is a small, obligate intracellular bacterium that cannot be cultured on standard media or visualized with the Gram stain. Because of the high infectivity of the organism, cultures should be attempted only by experienced personnel in Biosafety Level-3 laboratories. At present, the diagnosis usually relies on a fourfold rise in antibody titer from acute to convalescent serum samples. Nucleic acid testing is likely to provide a more rapid diagnosis, which would be useful in guiding treatment decisions.

Although patients may be acutely ill on presentation, the disease is rarely fatal and generally runs its course in 1 to 2 weeks.¹⁹⁴ Some patients, particularly older adults, have a very prolonged illness. The most concerning aspect of Q fever is the potential for chronic vascular complications including endocarditis, vascular graft infections, and infected aortic aneurysms. Acute Q fever pneumonia during pregnancy is often associated with fetal loss.

Tetracyclines, especially doxycycline, are first-line therapy for Q fever. Quinolones have excellent in vitro activity and may be advantageous in the treatment of meningoencephalitis.¹⁹⁵

NOCARDIOSIS

Nocardia asteroides is the etiologic agent in more than 80% of pulmonary or disseminated cases of nocardiosis, although several other species (e.g., *Nocardia brasiliensis*) have also been associated with human infection. The organisms are widespread in nature, primarily in soil. The respiratory tract, skin, and gastrointestinal tract are portals of infection. Dysfunction of cell-mediated immunity and, to a much lesser extent, immunoglobulin defects predispose to infection. Thus, the infection rate is increased in patients who have lymphoma or leukemia, Cushing disease, or AIDS, or who are receiving immunosuppressive medications. The most recent cases have been reported in lung, heart, or stem-cell transplant recipients. Persons with pulmonary

alveolar proteinosis are also at increased risk. Nonetheless, approximately half of the patients in whom nocardiosis develops have no known underlying medical disorder.

Although nocardiosis and actinomycosis are clinically similar infections of the lower respiratory tract, nocardiosis can be distinguished by less proclivity for sinus tract formation and a greater tendency for hematogenous dissemination in both healthy and impaired hosts. Dissemination may involve almost every organ system, but the central nervous system and skin are most common.¹⁹⁶ Many patients with pulmonary nocardiosis have low-grade fever, fatigue, weight loss, productive cough, and pleuritic chest pain for weeks before seeking medical attention. However, some immunosuppressed patients present with acute, fulminant pneumonia. Physical examination is nonspecific unless sites of dissemination are obvious. Neurologic signs of a mass lesion may be present. Cutaneous dissemination appears as multiple subcutaneous abscesses with or without sinus tracts. Imaging commonly demonstrates localized bronchopneumonia or lobar consolidation (eFig. 33-25), but there may also be solitary, multiple (eFig. 33-26), or miliary nodules, and abscesses (eFig. 33-27). Pleural effusion develops in up to one third of cases.

Nocardia species are gram-positive bacilli that appear as beaded, branching filaments. Unlike the anaerobic Actinomycetaceae, *Nocardia* requires aerobic growth conditions and is usually weakly acid-fast when stained by the modified Ziehl-Neelsen method (eFig. 33-28). *Nocardia* can be cultivated on conventional blood agar or Sabouraud medium but growth may not be apparent for 3 to 21 days. Although an occasional colonizer of the upper respiratory tract, recovery of *Nocardia* from a culture of sputum or invasively obtained material is highly suggestive of the diagnosis.

Mortality approaches 50% in those with central nervous system lesions but is less than 10% in those with only pulmonary disease.¹⁹⁶ Because of in vitro synergy, TMP-SMX has become the standard treatment.¹⁹⁶ In case of a sulfa allergy or a resistant organism, minocycline, amikacin, cefotaxime, imipenem, or linezolid may be useful, but choices should always be guided by the results of susceptibility testing.¹⁹⁶ Prolonged therapy is needed to prevent relapse. Adequate drainage or excision of abscesses and empyema is a crucial adjunct to antimicrobial therapy.

MELIOIDOSIS (*BURKHOLDERIA PSEUDOMALLEI*)

In endemic areas such as Southeast Asia and northern Australia, melioidosis may be the most common cause of severe CAP.¹⁹⁷ *B. pseudomallei* is found in soil, vegetation, and water throughout tropical regions between latitudes 20 degrees N and 20 degrees S.^{48,198} Acquisition of the organism is through cutaneous inoculation or inhalation in patients with regular contact with water and soil.⁴⁸ Risk factors for disease include diabetes, alcoholism, and renal disease. Typhoons or episodic heavy rain may increase the risk of acute fulminant pneumonia; more than 75% of cases happen during the rainy season.¹⁹⁸

Melioidosis can produce either acute fulminant pneumonia or indolent, cavitary disease. Clinical manifestations of acute melioidosis include high fever, prostration, dyspnea, pleuritic chest pain, purulent sputum, and

hemoptysis. Concomitant bacteremia is common.¹⁹⁷ The chest radiograph typically shows diffuse miliary nodules, which may expand and cavitate. Subacute or chronic *B. pseudomallei* pneumonia is milder and often manifests after a period of latency. Patients may be entirely asymptomatic (i.e., abnormal radiograph only), or present with an illness clinically and radiographically indistinguishable from tuberculosis.

B. pseudomallei is an aerobic gram-negative bacillus that grows readily on routine culture media. Despite improvements in recognition and treatment, melioidosis is still associated with high morbidity and mortality.¹⁹⁷ *B. pseudomallei* is not sensitive to the usual CAP antibiotics but is usually susceptible to carbapenems, ceftazidime, and TMP-SMX. Optimal treatment for disseminated or life-threatening melioidosis requires initial intensive therapy with a carbapenem or ceftazidime followed by 3 months of TMP-SMX.^{48,197,199}

RHODOCOCCLUS EQUI

Rhodococcus equi may cause lung abscess and pneumonia. Most cases are seen in the setting of impaired cell-mediated immunity (e.g., high doses of corticosteroids, HIV infection, solid organ transplantation)²⁰⁰ and in persons with a history of animal exposure. Illness develops subacutely, mimicking mycobacterial or fungal infection. Chest radiographs often show upper lobe nodules that gradually cavitate.

The organism is an intracellular gram-positive bacillus. It may stain weakly acid-fast but is much smaller than mycobacteria. The most effective regimens appear to be prolonged courses of vancomycin or erythromycin. Addition of rifampin may be useful.

PULMONARY ANTHRAX (*BACILLUS ANTHRACIS*)

(see Chapter 40)

Although *B. anthracis* is detected in many agricultural regions, anthrax is a rare infection in the developed world. Spores, the transmissible agent of infection, reside in soil, water, and vegetation and primarily infect large herbivorous animals (e.g., cows, sheep, and horses). Humans are infected by spores via contact with contaminated animals or animal products (e.g., animal hides and wools).³³ *B. anthracis* is a proven agent of bioterrorism.²⁰¹⁻²⁰³

The manifestations of anthrax are cutaneous, gastrointestinal, and inhalational (wool sorter's disease); inhalational anthrax is the most severe. Disease results from germination of *B. anthracis* spores in the lungs or draining lymph nodes, followed by growth of the vegetative forms of the bacteria and production of edema toxin and lethal toxin. Clinical illness begins insidiously with fever, malaise, nonproductive cough, and precordial pain. This stage is followed by rapid pulmonary deterioration with dyspnea, stridor, chest pain, tachypnea, cyanosis, nausea, vomiting, and drenching night sweats. Diffuse edema of the neck and anterior chest may be evident, due to the action of edema toxin. Meningitis is a common complication.

Radiographically, the lung parenchyma is initially clear. A widened mediastinum and bilateral pleural effusions are clues to inhalational anthrax. Mediastinal widening is seen in 100% of inhalational anthrax cases,²⁰⁴ although a chest

CT scan may be required to define these characteristics.⁵¹ Later findings include vascular engorgement and lung parenchymal opacities.

B. anthracis is a large, facultative, gram-positive rod that forms spores. The organism grows readily on routine culture media and can be rapidly recovered from cultures of blood, sputum, and pleural fluid. In advanced disease, the organism may be demonstrated by Gram stain of peripheral blood.⁵¹ *B. anthracis* can be detected in nasal swabs of persons exposed to anthrax spores; the predictive value of this test for diagnosing clinical disease is ill-defined.⁵¹

Treatment recommendations for inhalational anthrax may be affected by resistance and the potential need to treat mass casualties. Current recommendations for inhalational anthrax call for initial treatment with ciprofloxacin plus one or two additional antibiotics with in vitro activity, such as clindamycin, vancomycin, imipenem, meropenem, chloramphenicol, penicillin, ampicillin, rifampin, and clarithromycin.²⁰⁵ If the isolate is susceptible, therapy can be changed from the fluoroquinolone to high-dose penicillin G or doxycycline. Intravenous therapy may be converted to oral therapy once the patient's condition stabilizes. Since pulmonary and systemic anthrax are associated with high mortality rates, therapy with an FDA-approved humanized monoclonal antibody (Raxibacumab) to anthrax lethal toxin is recommended as an adjunct to antimicrobial therapy.^{51a} Treatment for 60 days is recommended, to eliminate spores that could be the source of relapse. Although the reported mortality rate has been as high as 90%, 6 of 11 patients with inhalational anthrax survived during the 2001 anthrax attacks in the United States.⁵¹

TULAREMIA (*FRANCISELLA TULARENSIS*)

(see Chapter 40)

Although *F. tularensis* has been recovered from numerous insects and species of wild or domestic mammals throughout the temperate zones of the Northern Hemisphere, fewer than 200 cases of tularemia per year are reported in the United States.⁵² Humans acquire infection following direct contact with tissues of an infected animal (as when skinning or eating an infected animal), through the bite of an infected tick or deerfly, or by inhalation of contaminated aerosols.^{47,52,206} Persons engaged in landscaping or agricultural activities that generate aerosols in endemic areas are at particular risk for development of pneumonic tularemia.⁴⁷ Because of the efficiency of aerosol transmission, *F. tularensis* is regarded as a potential agent of bioterrorism.⁵²

Pneumonia develops from inhalation of contaminated aerosols or as a complication of bacteremia. Clinical manifestations typically begin abruptly with fever, chills, malaise, and headache. Shortly thereafter, dyspnea, cough, and chest pain may develop.⁵² Chest radiographs are usually normal at the onset (3 to 5 days following aerosol exposure) but ultimately show diffuse bronchopneumonia, often with hilar adenopathy.⁵² Pleural effusion is common and may be seen without parenchymal involvement.⁵²

F. tularensis is a fastidious, pleomorphic, gram-negative bacillus rarely visualized on Gram stain of sputum and requires specially enriched media for optimal recovery by culture. Because of the hazardous nature of the organism,

culture is best undertaken by reference laboratories. The organism can also be rapidly identified in tissues, secretions, and exudates by use of immunohistochemical techniques.⁵² Retrospective diagnosis can be accomplished by demonstrating a fourfold rise in agglutinating titers. A single titer of 160 or greater is compatible with either past or current infection.

Mortality can be as high as 60% if pneumonic tularemia is not suspected and treated appropriately. Although gentamicin has been used successfully, streptomycin remains the preferred therapy.⁵² Ciprofloxacin is an acceptable alternative agent; doxycycline and chloramphenicol are associated with higher relapse rates and require a longer duration of therapy.⁵² Ceftriaxone is unsatisfactory despite in vitro activity. After a known aerosol exposure to *F. tularensis*, prophylaxis with doxycycline or ciprofloxacin for 14 days is recommended.⁵²

PLAGUE (*YERSINIA PESTIS*) (see Chapter 40)

Plague is typically associated with ground squirrels, rabbits, prairie dogs, rats, and other small ground animals. Rodent fleas are responsible for transmission of the organism between animal hosts. Humans become infected when bitten by an infected rodent flea, by handling an infected animal carcass, or by inhaling an aerosol from a human or animal with pulmonary involvement. In the United States, most cases of plague are in rural New Mexico, Arizona, and California.⁴⁶ Because of the disease severity and potential for aerosol transmission, *Y. pestis* is also regarded as a potential bioterrorism weapon.²⁰⁷

Three clinical forms of infection exist: pneumonic, bubonic, and septicemic. Although the pneumonic form presents as a primary pneumonia, the lung may also be involved in bubonic and septicemic infections. Plague pneumonia may develop 2 to 7 days after the initial exposure. Early in the course of the illness, patients experience fever and toxicity, followed by chest pain, productive cough, dyspnea, and hemoptysis. The presence of hemoptysis can cause confusion with the hantavirus pulmonary syndrome, whose geographic distribution overlaps with plague in the United States. If pulmonary disease complicates bubonic plague, painful adenopathy is also noted. In the septicemic form, the patient may show only signs of septic shock. Chest radiographs in cases of pneumonic plague commonly reveal bilateral lower lobe alveolar opacities, but there may also be nodules, adenopathy, and pleural effusions.

Y. pestis is a short, nonmotile, gram-negative rod. Most patients with pneumonic plague have positive blood cultures. In addition, the organism can be recovered from sputum and lymph node aspirates by routine bacteriologic techniques. Fluorescent antibody staining of sputum and tissues facilitates the rapid diagnosis of plague but is available only in specialized laboratories.

Because of the potential for person-to-person transmission, all patients with plague pneumonia should be isolated. Recommended treatment consists of gentamicin or doxycycline.^{207,208} Alternative treatments include fluoroquinolones, streptomycin, or chloramphenicol. For all regimens, the duration of treatment is a minimum of 10 days.

MORAXELLA CATARRHALIS

M. catarrhalis causes pneumonia, acute exacerbations of COPD, otitis media, and maxillary sinusitis.²⁰⁹ Pneumonia typically is seen in patients with underlying COPD, although alcoholism, malnutrition, increased age, congestive heart failure, and malignancy are also risks.²⁰⁹

Because *M. catarrhalis* is part of the normal upper respiratory tract flora, only adequately screened sputum samples provide useful diagnostic information. A purulent specimen that contains many intracellular gram-negative diplococci and yields heavy growth of *M. catarrhalis* is highly suggestive of true pneumonia. Blood cultures are rarely positive.²⁰⁹

The mortality of *M. catarrhalis* is approximately 10%, primarily due to exacerbations of severe underlying pulmonary disease.²⁰⁹ Effective agents include TMP-SMX, cephalosporin, macrolide, tetracycline, quinolone, or β -lactam/ β -lactamase inhibitor combination. Virtually all isolates are resistant to penicillin and ampicillin because of β -lactamase production.

NEISSERIA MENINGITIDIS

N. meningitidis pneumonia is often a surprising culture diagnosis because clinical manifestations of meningococcal pneumonia resemble those of pneumococcal pneumonia. The estimated incidence of sporadic primary meningococcal pneumonia is 0.4 cases per 100,000 adults per year; pneumonia also complicates 5% to 15% of invasive meningococcal infections.²¹⁰ Asymptomatic carriage rates vary according to the season and are increased under conditions of crowding.²¹⁰ The organism is transmitted from person-to-person largely through droplet aerosols. Nosocomial clusters of meningococcal pneumonia are well described.

N. meningitidis is a gram-negative diplococcus; its appearance in sputum is similar to that of *Moraxella* and *Acinetobacter*. Rates of isolation of the organism from blood, cerebrospinal fluid, and pleural fluid from patients with meningococcal pneumonia are highly variable.

Aqueous penicillin G for 10 days, in daily doses of 4 to 6 million units, is adequate therapy for isolated pneumonia. Coexistence of septicemia or meningitis warrants increasing the dose to 18 to 24 million units per day. Isolates with decreased susceptibility to penicillin are not yet a significant problem in the United States, but have been reported in Europe and Africa.²¹¹

Because meningococci can be transmitted from patients with pneumonia to susceptible contacts, respiratory droplet isolation should be implemented during the initial days of treatment. Prophylaxis with ceftriaxone, ciprofloxacin, or rifampin is advised for household and other intimate contacts of the patient, including health care providers who have been exposed to respiratory secretions.

PASTEURELLA MULTOCIDA

Pasteurella multocida is part of the normal oral flora of many domestic and wild mammals. Although skin and soft tissue infections following a cat or dog bite are the more common

manifestations of human infection, sporadic cases of pneumonia, lung abscess, and empyema are seen in patients with chronic respiratory diseases, including COPD, carcinoma, and bronchiectasis. Most patients recall prior exposure to animals.

Pasteurella pneumonia is indistinguishable from other etiologies of CAP, although empyema may be more frequent. The organism is a small, gram-negative coccobacillus indistinguishable from other gram-negative rods by Gram stain.

Identification of the organism by culture of sputum, blood, and pleural fluid is easily accomplished.

The treatment of choice for *P. multocida* pneumonia is penicillin G, 4 to 12 million units daily for 10 to 14 days. Tetracycline, amoxicillin-clavulanate, second- and third-generation cephalosporins, TMP-SMX, fluoroquinolones, and chloramphenicol are also active. *P. multocida* is resistant to clindamycin and macrolides.

C-reactive protein, have also been found useful for predicting inadequate response. Initial higher levels of PCT or C-reactive protein represent a risk factor for inadequate response (odds ratio, 2.6),²¹³ whereas low levels are associated with responses to therapy. A recently described biomarker, MR-proadrenomedullin, has shown a greater association with severity assessment, and levels greater than 1.8 were associated with subsequent deterioration and ICU admission.²¹⁴

The causes of nonresponding pneumonia are classified as infectious, noninfectious, and of unknown origin.²¹² eTable 33-5 lists common infectious and noninfectious causes.

INFECTIOUS CAUSES

In patients hospitalized for CAP, specific infections are responsible for 40% of nonresponding cases. The most frequent microorganisms found are *S. pneumoniae*, *Legionella*, *P. aeruginosa*, and *S. aureus*.

Patients with CAP, HAP, or VAP may fail to respond because of resistance to the empirical antibiotic regimen selected. *P. aeruginosa*, which is not covered by empirical therapy for CAP, causes about 10% of cases of nonresponding CAP.²¹² Up to 50% of episodes of nonresponding VAP are caused by multiresistant microorganisms; the most frequent causes are MRSA, *P. aeruginosa*, carbapenemase-producing *Klebsiella*, and *Acinetobacter* species.²¹⁵

More unusual microorganisms in nonresponding CAP²¹² include *Mycobacteria*, *Nocardia* species, anaerobes, fungi, *Pneumocystis jirovecii*, and other organisms requiring antibiotics other than those recommended for CAP or HAP (eFig. 33-29). Investigation of the etiology of some of these microorganisms requires intensified microbiologic diagnostic testing as well as exhaustive review to search for risk factors, including epidemiology (travel, professional, leisure, or animal exposures), personal habits, and environmental factors.

Local or metastatic infectious complications also contribute to treatment failure. Empyema (see eFig. 33-7) is one of the most frequent complications in pneumonia and is thus a cause of nonresponse that must be evaluated with thoracentesis when a pleural effusion is present. Other causes of treatment failure are abscess formation (see eFig. 33-4) and necrotizing pneumonia (see eFigs. 33-20 and 33-21). Metastatic infections such as endocarditis, arthritis, pericarditis, meningitis, or peritonitis can contribute to treatment failure and are more common in bacteremic pneumonia. In approximately 30% of the cases, no specific cause for lack of response can be identified despite adequate antibiotic treatment. This may be due to the presence of comorbidities or to an exaggerated or diminished inflammatory response.^{215a}

NONINFECTIOUS CAUSES

Noninfectious diseases with acute involvement of the pulmonary parenchyma may simulate pneumonia. These include pulmonary infarction, pulmonary hemorrhage, organizing pneumonia, eosinophilic pneumonia, hypersensitivity pneumonitis, drug-induced lung disease, and neoplasms. Alveolar cell lung cancer (eFig. 33-30 and Video

33-2) may be particularly difficult to distinguish radiographically from pyogenic pneumonia. The frequency of noninfectious etiologies has been reported to be 22% in CAP²¹² and 19% in nosocomial pneumonia.²¹⁵ eTable 33-5 summarizes infectious and noninfectious causes of nonresponding pneumonia.

DIAGNOSTIC EVALUATION

The diagnostic approach to treatment failure requires a complete reevaluation of the history, physical examination, and laboratory studies including factors that may be related to delayed response.^{212,216} Reconsideration of the initial diagnosis is also an important component of the diagnostic approach. Important epidemiologic clues may suggest unusual microorganisms along with unexpected resistance to antimicrobials, or underlying immunodeficiency such as HIV infection.

MICROBIOLOGIC STUDIES

The microbiologic investigation of treatment failures requires comprehensive reexamination of initial microbiologic results, together with obtaining new samples for culture and other assays (eTable 33-6). Invasive techniques (i.e., bronchoscopy) for microbiologic samples and local evaluation of airways are recommended if they are not contraindicated. Both protected sheath brush and BAL sampling should be done during the same procedure for bacterial cultures, direct fluorescent antibody staining, and nucleic acid testing. Although culture results may be altered by the prior administration of antibiotics, the sensitivity of brush or BAL cultures approaches 40% in nonresponding CAP. In patients undergoing mechanical ventilation, the tracheal aspirate can provide diagnostic information. Gram stain of cytocentrifuged BAL fluid can rapidly identify intracellular microorganisms⁸⁸ and may guide decisions regarding changes in antimicrobial therapy. Comprehensive microbiologic studies should also be performed on samples from nonrespiratory sites (eTable 33-7). When present, pleural fluid should be obtained for culture, direct fluorescent antibody, and nucleic acid testing for likely pathogens. The role of transbronchial biopsy is not established, and its indication depends on the possible alternative diagnosis suspected.

Imaging Studies

Chest radiographs may demonstrate complications such as pleural effusion, cavitation, or new opacities. Chest CT scans provide a more detailed study of the parenchyma, interstitium, pleura, and mediastinum, potentially suggesting specific microorganisms (see eFig. 33-29) or alternative diagnoses. In a patient with applicable risk factors, the appearance of nodular images with the halo sign (i.e., a nodule surrounded by a halo of ground-glass attenuation, especially near the pleura) on CT scan is suggestive of pulmonary aspergillosis (see Chapter 91 and eFigs. 91-8A and 91-10) or mucormycosis (see Chapters 38, 91, and 95 and eFig. 91-9).^{217,218} Nodules of similar appearance have also been described in cytomegalovirus infection (see Chapter 91 and eFig. 91-2), granulomatosis with polyangiitis (formerly Wegener granulomatosis), Kaposi sarcoma, and

*Quantitative criteria for the interpretation of PSB and BAL specimens are described in the text.

BAL, bronchoalveolar lavage; PSB, protected specimen brush.

metastases with necrosis and/or hemorrhage. Ground-glass opacities consistent with interstitial pneumonia suggest *P. jirovecii* pneumonia. Nodules or multiple masses with or without cavitation are compatible with *Nocardia* species, *M. tuberculosis*, or Q fever. Diffuse or mixed interstitial and alveolar opacities may be due to viral infections or *M. pneumoniae*. Other imaging studies, such as chest CT pulmonary angiography should be considered to evaluate the possibility of pulmonary emboli.

THERAPEUTIC MANAGEMENT

Correction of Host Abnormalities

Defects related to the host's immune system may impede recovery from pneumonia. Immunodeficiency may arise as a complication of cancer chemotherapy, immunosuppressive agents, or corticosteroid use; or it may result from a congenital (e.g., agammaglobulinemia) or acquired (e.g., HIV infection) immune defect. Many of these immune deficiencies are not remediable; however, drug-related immunosuppression may be improved by discontinuing the offending agent or reducing the dose. Although reduction of immunosuppression may promote recovery from the active infection, it can also be complicated by enhanced inflammation due to immune reconstitution.^{219,220}

Granulocytopenia (absolute granulocyte count less than 500 cells/mm³) has been associated with fulminant, antibiotic-unresponsive pneumonia, and administration of *granulocyte colony-stimulating factor* (G-CSF) or *granulocyte-macrophage colony-stimulating factor* (GM-CSF) is effective in increasing the number of circulating neutrophils. Despite this effect on neutrophils, routine administration of G-CSF or GM-CSF has not been found to improve survival from infections.²²¹ Because pneumonia is the infection most frequently associated with a poor clinical outcome in profoundly neutropenic patients, the use of G-CSF or GM-CSF in these patients may be justified, even though a benefit has not been demonstrated.²²² Corticosteroid treatment has been investigated because of its suppressant effect on inflammatory responses; studies have yielded discordant findings. A recent meta-analysis found evidence for a positive effect on survival in severe cases of CAP.²²³ In contrast, a recent randomized trial showed no benefit, although the number of patients with severe CAP may have been insufficient to reveal a difference in this select group.²²⁴

Antimicrobial Adjustment

The optimum therapeutic approach to nonresolving pneumonia requires close monitoring, transfer to a higher level of care, and optimization of the antibiotic regimen, including dosing.²¹² The optimal time to make these changes is not defined, although it has been suggested that one should wait until 72 hours after the initiation of treatment except in the presence of severe clinical deterioration or dramatic progression as determined by chest radiograph. Before initiating a change in antibiotics, new samples should be obtained for microbiologic studies.

In nonresponding CAP, strong consideration should be given to extending the antibacterial spectrum to ensure coverage of resistant *S. pneumoniae*, *P. aeruginosa*, *S. aureus*, and anaerobes. Such broad-spectrum therapy should be

undertaken after all abscesses or empyemas have been drained, the results of all previous cultures are reviewed and, whenever possible, vigorous new efforts have been made to identify the responsible microorganisms. The specific antimicrobial regimen chosen depends on patient risk factors, disease severity, and the local epidemiology of antimicrobial resistance. In community-acquired MRSA, antimicrobial treatments may include linezolid or clindamycin plus vancomycin, depending on results of susceptibility testing.^{21,163}

In nonresponding nosocomial pneumonia, combinations of up to three antibiotics may be necessary to cover *P. aeruginosa*, MRSA, and the endemic flora of each hospital, such as *Acinetobacter* species or other microorganisms.²¹⁵ The increasing spread of virulent carbapenemase-producing *K. pneumoniae* also necessitates vigilance for these organisms and consideration of combinations of polymyxin B or E, tigecycline, and/or ampicillin-sulbactam.²²⁵ Occasionally, empirical coverage against *Aspergillus* species should be considered (i.e., severe COPD, significant immunosuppressive therapy, corticosteroid treatments), especially if supported by clinical, radiologic,²¹⁷ or laboratory data. The recommended approach is to cover empirically all likely causal microorganisms while awaiting the results of repeated respiratory samples and then adjust and deescalate antibiotics accordingly.

LUNG ABSCESS

Lung abscesses are pus-containing necrotic lesions of the lung parenchyma that result from aspiration of bacteria-laden secretions and show an air-fluid level (see Fig. 33-13). Lung abscesses are distinct from, and may follow, necrotizing pneumonia, in which multiple small cavities develop in contiguous areas of the lung.^{226,227} Lung abscesses must be distinguished from septic pulmonary emboli, which are often multiple and bilateral, involve the lower lobes (see Fig. 33-6), and are secondary to an endovascular infection.

Unlike most other respiratory infections that are caused by single pathogens, lung abscesses are caused by mixed populations of bacteria. The most common components of the mixed bacterial populations in lung abscesses are anaerobic bacteria (principally *Peptostreptococcus* species (now termed *Finegoldia magna*), *E. nucleatum*, and *Prevotella melaninogenica* (formerly *Bacteroides melaninogenicus*)). Microaerophilic streptococci and viridans streptococci are also frequently isolated and can contribute to treatment failure if appropriate antibiotics are not included.²²⁸ Lung abscess may also be associated with pyogenic bacteria, mycobacteria, fungi, and parasites such as *Paragonimus*, *Entamoeba*, and *Echinococcus* (see Chapter 39). Secondary lung abscesses develop from congenital lung abnormalities, obstructing neoplasms, foreign bodies, and bronchiectasis. Lung abscess may also complicate pulmonary infarction, primary lung cancer (central carcinoma with necrosis), metastatic malignancies, and the necrotic conglomerate lesions of silicosis and coal miners' pneumoconiosis. Lesions in diseases such as granulomatosis with polyangiitis (formerly termed Wegener granulomatosis) and rheumatoid arthritis with rheumatoid nodules may also mimic lung abscess.

The clinical manifestations of lung abscesses are distinct from those of CAP, because they are usually prolonged in time (2 weeks to 3 months or more) and include fever, night sweats, cough with foul-smelling sputum, fatigue, weight loss, and sometimes hemoptysis.

The typical appearance of a lung abscess on a chest radiograph is a thick-walled cavity with an air-fluid level (see Fig. 33-13 and eFigs. 33-4A, 33-13A, and 33-15). A contrast-enhanced CT is occasionally necessary to differentiate lung abscess from other conditions, and bronchoscopy may be needed to distinguish lung abscess from endobronchial carcinoma.

Antibiotics with activity against anaerobic and aerobic bacteria and that are unaffected by the β -lactamases produced by anaerobes are the mainstay of treatment for lung abscesses.²²⁸ Clindamycin has been widely used and is superior to penicillin alone, undoubtedly because of the increasing prevalence of β -lactamase production by the anaerobes that cause lung abscesses. More recently, β -lactam/ β -lactamase inhibitor combinations (amoxicillin-clavulanate or ampicillin-sulbactam) have been found to provide cure rates indistinguishable from those with clindamycin; moxifloxacin and carbapenems have also been used successfully.²²⁸ Metronidazole alone is not recommended, because it lacks sufficient activity against microaerophilic streptococci and viridans streptococci that are often part of the mixed microbial flora in lung abscesses. If metronidazole is used, penicillin should be added to cover streptococci. The optimal duration of antibiotic treatment has not been determined, although treatment for 6 to 8 weeks is commonly employed.

Failure to respond to antibiotics within 7 to 10 days warrants investigation for alternative diagnoses or complications. Antibiotic treatment may fail if the patient has immunodeficiency, if the cavity is large (>8 cm), or if the abscess is due to pyogenic bacteria such as *P. aeruginosa* or *S. aureus*. CT-guided percutaneous transthoracic tube drainage²²⁹ or endoscopic drainage²³⁰ are alternatives to surgical resection; the reported success rates with both of these procedures are high, although no prospective controlled trials have been reported. Complications of CT-guided tube drainage include pneumothorax, pyopneumothorax, and bronchopleural fistula. After drainage, patients show clinical improvement usually in 48 hours. Persistent fever can also be seen if there is a secondary pleural empyema that requires drainage.

PREVENTION OF PNEUMONIA

VACCINES

Prevention of pneumonia may be achieved by administering the influenza and pneumococcal vaccines. Recommendations for administration of influenza²³¹ and pneumococcal²³² vaccines are presented in eTable 33-8 and eTable 33-9, respectively.

Inactivated influenza vaccination is recommended annually for all persons aged 6 months and older, including pregnant women. For those averse to injections, a live attenuated influenza vaccine can be given by intranasal administration to healthy persons 5 to 49 years old. The live attenuated

vaccine must be avoided in pregnancy, in high-risk persons with chronic underlying diseases or immunodeficiencies, and in health care staff taking care of immunosuppressed patients; it is not approved for use in those older than 49 years. While annual influenza vaccination is widely recommended, the immunogenicity and efficacy of the currently available vaccine is lower in individuals older than 65 years of age, and breakthrough infections are frequent.²³²

Two pneumococcal vaccines are currently available. The purified polysaccharide vaccine (PPSV23) contains capsular antigens isolated from 23 of the most prevalent capsule types and is immunogenic in adults, although antibody levels decrease to prevaccination levels after 4 to 7 years. The pneumococcal conjugate vaccine (PCV13) contains the polysaccharide antigens from 13 of the most prevalent capsule types, conjugated to a nontoxic mutant of diphtheria toxin protein, which generates T-cell help and long lived memory B cells specific for the pneumococcal antigens. PPSV23 should be administered to all individuals 65 years of age and older, as well as those 19 to 64 years of age with chronic conditions that increase the risk of invasive pneumococcal infection (e.g., diabetes mellitus, chronic lung, heart, or liver disease; cigarette smoking or alcoholism). Patients aged 19 years and older with immunodeficiencies or other conditions that impose an especially high risk of invasive pneumococcal infection (asplenia, HIV or other congenital or acquired immunodeficiencies, myeloma, lymphoma, leukemia, chronic renal failure) should receive an initial dose of PCV13 followed 8 weeks or longer later by PPSV23. eTable 33-9 lists the conditions and indications for which administration of each of the pneumococcal vaccines is currently recommended.²³³ In 2014, the updated ACIP recommendations are that both PCV13 and PPSV23 should be administered in series to all adults 65 years of age and older. A dose of PCV13 should be received first followed by a dose of PPSV23 6 to 12 months later. Individuals previously vaccinated with PPSV23 should be given a dose of PCV13 after approximately 1 year.^{234,235}

SMOKING CESSATION

Not only is smoking a risk factor for pneumococcal disease, quitting smoking reduces the risk.²³⁶ The IDSA/ATS recommend smoking cessation counseling as well as pneumococcal vaccination for smokers who are hospitalized with pneumonia.¹⁸

Key Points

- All patients with suspected pneumonia should have a chest radiograph. Gram stains of sputum and cultures of blood, sputum, and other sites should be obtained in hospitalized patients before treatment. *S. pneumoniae* and *L. pneumophila* urinary antigens can make an etiologic diagnosis with reasonable sensitivity and specificity.
- Aspiration is the cause of infection with *S. pneumoniae*, *H. influenzae*, gram-negative bacilli, and other organisms, whereas aerosolization is the route of infection with intracellular bacteria such as *M. pneumoniae*, *Chlamydophila* species, and *C. burnetii*. Aside from

eTable 33-8 Recommendations for Administration of Influenza Vaccine*

Inactivated vaccine: All persons aged 6 months and older including pregnant women

Live attenuated vaccine†: Healthy, nonpregnant women aged 2 to 49 years without high-risk medical conditions

*Avoid giving vaccine to patients with anaphylactic allergy to eggs or to other influenza vaccine components. The optimal period for vaccination is October to November. However, it is acceptable to provide vaccine from September to early March.

†Health care personnel who care for severe immunocompromised persons should receive inactivated rather than live vaccine.

Modified from Recommended Immunization schedule for adults aged 19 years and older. *MMWR* 62:Suppl, 2013.

eTable 33-9 Recommendations for PPSV23 and PCV13 by Risk Group for Adults 19 Years and Older*

Risk Group	PCV13 Recommended	PPSV23 Recommended	PPSV23 Revaccination 5 Years after First Dose
Immunocompetent	Cerebrospinal fluid leak Cochlear implant	Chronic heart diseases† Chronic lung diseases‡ Diabetes mellitus Chronic liver diseases Cerebrospinal fluid leak Cochlear implant Alcohol Smoking	
Asplenia	Sickle cell disease/ hemoglobinopathy Congenital or acquired asplenia	Sickle cell disease/ hemoglobinopathy Congenital or acquired asplenia	Sickle cell disease/ hemoglobinopathy Congenital or acquired asplenia
Immunocompromised	HIV Congenital or acquired immunodeficiency Chronic renal failure Leukemia/lymphoma Generalized malignancy Solid organ transplant Multiple myeloma Iatrogenic immunosuppression§	HIV Congenital or acquired immunodeficiency Chronic renal failure Leukemia/lymphoma Generalized malignancy Solid organ transplant Multiple myeloma Iatrogenic immunosuppression	HIV Congenital or acquired immunodeficiency Chronic renal failure Leukemia/lymphoma Generalized malignancy Solid organ transplant Multiple myeloma Iatrogenic immunosuppression

*All adults aged 65 years and older should receive PCV13 and PPSV23, with the sequence and interval depending on previous history of vaccination with pneumococcal vaccine.

†Including congestive heart failure and cardiomyopathies.

‡COPD, emphysema, and asthma.

§Including long-term systemic corticosteroids and radiation therapy.

Modified from Centers for Disease Control and Prevention: Tomczyk S, Bennett NM, Stoecker C, et al: Use of 13-valent pneumococcal conjugate vaccine and 23-valent pneumococcal polysaccharide vaccine among adults aged ≥ 65 years: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Morb Mortal Wkly Rep* 63(37):822–825, 2014.

inhalational pneumonia due to *Legionella* or contaminated medical aerosols, aspiration is the cause of hospital-acquired pneumonia, especially in intubated patients.

- Nucleic acid amplification tests should be used increasingly to diagnose viruses and fastidious bacteria, *M. pneumoniae*, *C. pneumoniae*, *L. pneumophila*, and *B. pertussis* because culture procedures are too insensitive and too slow to be relevant therapeutically.
- In older and immunocompromised patients, the signs and symptoms of pneumonia may be muted and overshadowed by nonspecific complaints. Temperature greater than 38.5° C or accompanied by chills should never be attributed to bronchitis without examining a chest radiograph. Older patients with pneumonia who present with altered mental status without fever often have a delay in receiving antibiotics; this delay can increase mortality.
- The treatment for pneumonia should be pathogen-directed, but definitive identification of the patient's causal pathogen may be difficult. Therefore, the setting in which the patient resides (e.g., community, hospital, nursing home), the severity of the disease, the age of the patient, the presence of comorbidities and immunosuppression, previous antimicrobial therapy, and specific clinical and radiologic manifestations of the illness are used to select initial empirical antimicrobial therapy.
- If the etiologic agent has been identified, the antimicrobial regimen should be adjusted based on the results of in vitro susceptibility testing. The ideal drug for a known pathogen has the narrowest spectrum of activity and is the most efficacious, least toxic, and least costly.

eFIGURE IMAGE GALLERY

eFigure 33-1 Lobar pneumonia due to pneumococcus. Frontal chest radiograph shows homogeneous increased opacity conforming to the shape of the right upper lobe, extending to the pleural surfaces, associated with air bronchograms (arrows). These findings are typical of air space consolidation, and the pattern is consistent with lobar pneumonia, commonly seen with pneumococcal or *Klebsiella* pulmonary infections. (Courtesy Michael Gotway, MD.)

eFigure 33-2 Atypical pneumonia due to adenovirus. Frontal chest radiograph in a pediatric patient shows multifocal, bilateral central peribronchial thickening, typical of an infiltrative process involving the pulmonary interstitium, such as viral infection. (Courtesy Michael Gotway, MD.)

eFigure 33-3 Aspiration pneumonia. **A**, Frontal chest radiograph shows right lower lobe consolidation and volume loss; note shift of trachea and cardio-mediastinal structures toward the right. Trace right pleural effusion is present. **B–E**, Axial chest CT displayed in lung windows shows right lower lobe consolidation associated with small centrilobular nodules (arrowheads) consistent with bronchopneumonia and bronchiolitis. This pattern is consistent with aspiration pneumonia, particularly when seen in dependent lung regions, but is not completely specific for aspiration; community-acquired or health care-acquired bronchopneumonia may appear similar. However, what is specific for aspiration in this circumstance is the frank aspiration of orally administered contrast (**E**, single arrow, oral contrast in right lower lobe bronchus; **D** and **E**, double arrows, oral contrast extending into right lower lobe pulmonary parenchyma), which flows directly into the affected regions of lung. (Courtesy Michael Gotway, MD.)

eFigure 33-4 Lung abscess. **A**, Frontal chest radiograph in a patient with cough and purulent sputum shows a thick-walled cavity with an irregular internal lining and air-fluid level in the left apex. **B–E**, Axial chest CT displayed in soft tissue windows shows a rounded area of low attenuation (*arrows*) in the left upper lobe, surrounded by consolidation consistent with a pulmonary abscess. The internal low attenuation is fluid density, and an air-fluid level is present, typical of pulmonary abscess. Reactive prevascular lymph node enlargement is also evident. (Courtesy Michael Gotway, MD.)

eFigure 33-5 Percutaneous transthoracic sampling of a pulmonary abscess. **A** and **B**, Axial chest CT shows placement of a needle into a left apical cavity (same patient as in [eFig. 33-4](#)). Purulent fluid was recovered, with microbiologic analysis disclosing polymicrobial infection. The lesion resolved with antibiotic therapy. (Courtesy Michael Gotway, MD.)

eFigure 33-6 Pneumococcal bronchopneumonia. **A**, Frontal chest radiograph shows patchy bronchovascular thickening (*arrows*) in the left lower lobe; trace blunting of the left costophrenic angle is present. **B**, Axial chest CT 2 days following **A** shows nodular lingular consolidation (*arrow*) and numerous small centrilobular nodules (*arrowheads*) consistent with bronchopneumonia. This bronchopneumonia pattern contrasts with the lobar pneumonia pattern (see [Fig. 33-1](#) and [eFig. 33-1](#)). Both imaging patterns may be seen with pneumococcal pneumonia. (Courtesy Michael Gotway, MD.)

Figure 33-7 *Streptococcus intermedius* pneumonia and empyema. **A**, Frontal chest radiograph shows right lung consolidation and volume loss. Some increased opacity adjacent to the chest wall suggests pleural disease but the findings are nonspecific. **B–E**, Axial chest CT displayed in an intermediate window to highlight the lung parenchyma and soft tissue features simultaneously, obtained shortly after **A**, shows a rounded gas collection containing fluid along the right chest wall consistent with empyema and bronchopleural fistula. *S. intermedius* was recovered following right thoracostomy tube placement. (Courtesy Michael Gotway, MD.)

eFigure 33-8 *Haemophilus influenzae* pneumonia: bronchiolitis. **A**, Frontal chest radiograph shows several nonspecific small nodular opacities bilaterally (*arrowheads*). **B**, Axial chest CT through the lung bases shows numerous small centrilobular nodules (*arrowheads*), some with branching configurations (*arrows*), the latter consistent with "tree-in-bud" opacity, representing infectious bronchiolitis. The appearance of small centrilobular nodules with branching configurations is not specific for *Haemophilus influenzae* pneumonia and can be seen with other bacteria and occasionally with fungi or even viruses. (Courtesy Michael Gotway, MD.)

eFigure 33-9 *Mycoplasma pneumoniae* pneumonia: multilobar pneumonia. **A**, Frontal chest radiograph shows right lower lobe consolidation (*arrow*) associated with several small nodular opacities (*arrowheads*), the latter consistent with "acinar" or "air space" nodules. **B**, Axial chest CT through the lower lungs displayed in lung windows shows extensive bilateral consolidation (*arrows*) associated with small nodules (*arrowheads*), varying from 3 to 4 mm to 1 cm in size. (Courtesy Michael Gotway, MD.)

eFigure 33-10 *Mycoplasma pneumoniae* pneumonia: unilateral bronchopneumonia. (Courtesy Michael Gotway, MD.)

eFigure 33-11 Methicillin-resistant *Staphylococcus aureus* pneumonia. **A,** Frontal chest radiograph in a patient subsequently proven to have methicillin-resistant *Staphylococcus aureus* (MRSA) pneumonia shows left lung consolidation (*arrows*) with internal lucency consistent with necrosis and cavitation. **B,** Axial chest CT displayed in lung windows shows left lower lobe consolidation with internal lucency (*arrows*) consistent with a necrotic pneumonia. The patient recovered following antibiotic therapy. (Courtesy Michael Gotway, MD.)

eFigure 33-12 *Klebsiella pneumoniae* bronchopneumonia. **A**, Frontal chest radiograph shows patchy right lower lobe opacity (arrows). **B–E**, Axial chest CT through the lower lobes displayed in lung windows shows patchy nodular opacities (arrows) consistent with bronchopneumonia but not specific for a microbial etiology. (Courtesy Michael Gotway, MD.)

eFigure 33-13 *Klebsiella pneumoniae* lung abscess. **A**, Frontal chest radiograph shows a subpleural right apical cavity (arrows) with an air-fluid level consistent with a pulmonary abscess. Axial chest CT displayed in soft tissue (**B**) and lung (**C**) windows shows a nonspecific cavity (arrows) consistent with a pulmonary abscess but not specific for a specific microbiologic etiology. (Courtesy Michael Gotway, MD.)

eFigure 33-14 *Pseudomonas aeruginosa* bronchopneumonia. A–C, Axial chest CT through the lower lobes displayed in lung windows shows nodular consolidation (A and C, arrows) and numerous small centrilobular nodules with branching morphologies consistent with “tree-in-bud” opacities (arrowheads). (Courtesy Michael Gotway, MD.)

eFigure 33-15 *Pseudomonas aeruginosa* cavitary pneumonia. Frontal chest radiograph in a patient with *P. aeruginosa* pneumonia shows a large right upper lobe thick-walled cavity (arrows). (Courtesy Michael Gotway, MD.)

eFigure 33-16 *Pseudomonas aeruginosa* cavitary pneumonia. Axial chest CT displayed in lung windows of a patient with *P. aeruginosa* pneumonia shows several small, relatively thin-walled peripheral right upper lobe cavities (arrows). (Courtesy Michael Gotway, MD.)

eFigure 33-17 *Legionella pneumophila* pneumonia: multilobar pneumonia. Frontal chest radiograph in a patient with *Legionella* pneumonia and respiratory failure shows left-greater-than-right multilobar consolidation. (Courtesy Michael Gotway, MD.)

eFigure 33-18 Aspiration pneumonia: bronchopneumonia/bronchiolitis appearance at chest CT. A and B, Axial chest CT through the lower lobes displayed in lung windows in a patient with swallowing dysfunction shows numerous small centrilobular nodules, some with branching morphologies (arrowheads), and peribronchial consolidation (arrows). The imaging appearance is consistent with bronchopneumonia, but not specific for aspiration. Note resemblance of this CT appearance with *P. aeruginosa* pneumonia (see eFig. 33-14), *Haemophilus influenzae* pneumonia (see eFig. 33-8B), and pneumococcal bronchopneumonia (see eFig. 33-6). (Courtesy Michael Gotway, MD.)

eFigure 33-19 Aspiration bronchopneumonia: rapid appearance of new lung opacity at imaging and dependent lung involvement. Frontal chest radiograph performed at admission (**A**) shows clear lungs; several days later, following a witnessed aspiration event, the radiograph (**B**) shows development of multifocal peribronchial nodular foci (*arrowheads*). **C**, Lower thoracic images from an abdominal CT scan several weeks before **A** and **B** shows only minimal basal atelectasis. **D** and **E**, Axial chest CT through the lower lobes performed immediately following **B** shows peribronchial consolidation (**D**, *arrows*) and extensive lower lobe, dependent consolidation (**E**, *arrows*). Note volume loss, evidenced by posterior displacement of the major fissures. (Courtesy Michael Gotway, MD.)

eFigure 33-20 Anaerobic pneumonia. **A–D**, Axial chest CT in a patient with polymicrobial anaerobic pneumonia shows multifocal consolidation in the right middle lobe (**A** and **B**, *arrows*) and bilateral lower lobes. The soft tissue window images show the right middle lobe consolidation to be hypovascular; compare attenuation characteristics of the right middle lobe opacity (*arrows*, **B**) with the appearance of the lower lobe consolidation (*arrowheads*, **B**). After several days, the poorly defined hypovascular right middle lobe consolidation (**B**, *arrows*) evolved into discrete abscesses (**D**, *arrowheads*). (Courtesy Michael Gotway, MD.)

Figure 33-21 Evolution of pulmonary aspiration into lung abscess. **A**, Axial chest CT displayed in soft tissue windows performed shortly following a witnessed aspiration event shows extensive bilateral lower lobe consolidation (arrows). **B**, Contrast-enhanced chest CT performed several days following **A** shows developing necrosis and cavitation (arrowheads) within the lower lobe consolidation. **C** and **D**, Repeat contrast-enhanced chest CT performed over the ensuing week following **A** and **B** shows maturation of frank bilateral lower lobe pulmonary abscesses (arrowheads); note well-defined, enhancing walls surrounding these gas and fluid collections. **E**, Axial enhanced chest CT following 3 weeks of antibiotic therapy shows partial resolution of the bilateral lower lobe pulmonary abscesses (arrowheads). (Courtesy Michael Gotway, MD.)

Figure 33-22 Actinomycosis: cavitory nodule. **A**, Frontal chest radiograph shows right upper lobe consolidation and a poorly defined nodular opacity (arrow). **B**, Frontal chest radiograph 2 weeks following **A** shows resolution of the right upper lobe consolidation, now exposing a dominant cavitory right apical nodule with internal opacity (arrow), and small surrounding nodules (arrowheads). **C** and **D**, Axial chest CT displayed in lung windows performed within 1 day of the presenting chest radiograph (**A**) shows the right apical opacity as a cavitory nodule with an internal air-fluid level; surrounding ground-glass opacity and consolidation are present, as seen on the chest radiograph (**A**). **E** and **F**, Chest CT displayed in lung windows performed the same day as **B** shows the dominant right apical opacity with complex internal architecture (arrows) and confirms small surrounding nodules. Biopsy of this lesion recovered *Actinomyces israelii*. (Courtesy Michael Gotway, MD.)

eFigure 33-23 Actinomycosis: chest wall involvement. **A**, Frontal chest radiograph shows a right lower lung mass. This finding is nonspecific. **B**, Rib detail radiograph shows subtle periosteal reaction (arrowheads) with erosion of the inferior rib cortex (arrow) consistent with chest wall invasion. Biopsy of the right lung mass recovered *Actinomyces israelii*. (Courtesy Michael Gotway, MD.)

eFigure 33-24 Gram stain of an actinomycotic sulfur granule. **A**, Original magnification $\times 100$; **B**, original magnification $\times 400$. (Courtesy Michael Gotway, MD.)

eFigure 33-25 *Nocardia asteroides* pulmonary infection: consolidation. **A**, Axial chest CT shows extensive bilateral lower lobe consolidation and more anteriorly located interstitial thickening and ground-glass opacity. The right lower lobe consolidation was cavitary at a more inferior level. **B**, Axial chest CT in a different patient shows bilateral lower lobe masslike opacities (arrows); biopsy of the left lower lobe lesion recovered *Nocardia asteroides*. (Courtesy Michael Gotway, MD.)

eFigure 33-26 *Nocardia asteroides* pulmonary infection: multiple nodules. **A and B,** Axial chest CT in an immunosuppressed renal transplant recipient shows multiple bilateral nodules, many of which are solid-appearing (arrowheads), due to *N. asteroides*. **C–E,** Axial chest CT in another immunosuppressed renal transplant recipient shows ground-glass opacity nodules (arrowheads), also shown to be due to *N. asteroides*. (Courtesy Michael Gotway, MD.)

eFigure 33-27 *Nocardia asteroides* pulmonary infection: abscess. **A,** Frontal chest radiograph shows a poorly defined opacity (arrows) in the subpleural right upper lobe. **B and C,** Axial chest CT displayed in lung windows shows a subpleural right upper lobe cavity (arrows) containing an air-fluid level. This lesion is nonspecific in appearance and could be the result of a number of infections, but *N. asteroides* was recovered at biopsy. (Courtesy Michael Gotway, MD.)

eFigure 33-28 Modified acid-fast stain of sputum containing *Nocardia asteroides* shows filamentous branching organisms. (Courtesy Michael Gotway, MD.)

eFigure 33-29 An infectious cause of “nonresponding” pneumonia: amebic pleuropulmonary infection. **A**, Frontal chest radiograph in a 23-year-old man with fever and chest pain shows right lower lobe consolidation and a small-to-moderate right pleural effusion, presumed to represent pneumonia and parapneumonic effusion. **B** and **C**, Axial chest CT after the patient failed to respond to therapy for community-acquired pneumonia was performed to assess right pleural fluid drainage following thoracostomy tube placement (the thoracostomy tube is visible posteriorly in **B**). Chest CT performed through the right lower lung (**B**) shows consolidation with central low-attenuation (arrow), the latter consistent with a pulmonary abscess or area of necrosis. Chest CT through the extreme lung base and upper abdomen (**C**) shows a low attenuation focus (arrowhead) in the cranial liver (L), also consistent with an abscess. The liver and lung lesions are in close proximity to one another, suggesting that the liver lesion may have extended through the diaphragm to produce the lung findings; such behavior is typical of an amebic abscess. Further evaluation revealed that the patient recently immigrated to the United States from Mexico, and stool analysis recovered *Entamoeba histolytica* trophozoites. (Courtesy Michael Gotway, MD.)

eFigure 33-30 Noninfectious “nonresponding” pneumonia: invasive mucinous adenocarcinoma (formerly referred to as mucinous bronchioloalveolar carcinoma). **A**, Frontal chest radiograph in a patient with persistent shortness of breath shows right lower lobe consolidation. The patient was treated with broad-spectrum antibiotics for presumed community-acquired pneumonia. **B**, Repeat frontal chest radiograph 3 months following **A** shows no change in the appearance of the right lower lobe opacity. **C**, Axial chest CT through the right lung base shown in lung windows reveals relatively nonspecific subpleural consolidation with air bronchograms and reticulation associated with ground-glass opacity. **D**, Fused FDG-PET image shows the right lower lobe opacity to be hypermetabolic. Bronchoscopic evaluation did not disclose a specific diagnosis for the persistent right lower lobe opacity. Resection of the right lower lobe proved invasive mucinous adenocarcinoma. (Courtesy Michael Gotway, MD.)

Implementing a Structured Prevention Policy

INTRODUCTION

Ventilator-associated pneumonia (VAP) is the most frequent intensive care unit (ICU)-acquired infection among patients who are treated with mechanical ventilation.^{1,2} In contrast to infections of other organs (e.g., urinary tract and skin), for which mortality ranges from 1% to 4%, the mortality rate for VAP, defined as pneumonia occurring more than 48 hours after the onset of mechanical ventilation, ranges from 20% to 50%, and can even be higher when lung infection is caused by high-risk pathogens.¹⁻³ Although the attributable mortality rate for VAP is still debated, good evidence indicates that VAP prolongs the duration of mechanical ventilation and of the ICU stay.^{1,2} Approximately 50% of all antibiotics prescribed in an ICU are administered for respiratory tract infections.⁴ Because several studies have shown that appropriate antimicrobial treatment of patients with VAP significantly improves outcome, rapid identification of infected patients and accurate selection of antimicrobial agents are important clinical goals.¹ Agreement is lacking, however, about the appropriate diagnostic, therapeutic, and preventive strategies for VAP.

PATHOGENESIS

Multiple defense mechanisms protect the normal human respiratory tract from infection. Examples include anatomic barriers, such as the glottis and larynx; cough reflexes; constituents of tracheobronchial secretions; mucociliary clearance; epithelial lining fluid and surfactant components; cell-mediated and humoral immunity; a phagocytic system that involves alveolar macrophages and recruited neutrophils; and both humoral and cell-mediated adaptive immunity.^{5,6} When these coordinated components function properly, invading microbes are eliminated and clinical disease is avoided. When these defenses are impaired, or if they are overcome by a high inoculum of organisms or organisms of unusual virulence, pneumonitis results.

As suggested by the infrequent association of VAP with bacteremia, most of these infections appear to result from aspiration of potential pathogens that have colonized the

mucosal surfaces of the oropharyngeal airways, the dental plaque, and/or the paranasal sinuses.⁶ Endotracheal intubation not only compromises the natural barrier between the oropharynx and trachea, but also facilitates the entry of bacteria into the lungs by pooling and leakage of contaminated secretions around the endotracheal tube cuff from the subglottic area to below the true vocal cords.⁷ Contaminated secretions leak into the lungs of most intubated patients and may be facilitated by the supine position.⁸ Moreover, biofilm formation on the inner and outer surfaces of the endotracheal tube provides a protected environment for pathogens. Bacterial aggregates in biofilm dislodged during suctioning are dangerous for the lung, because they are difficult to clear by host immune defenses and difficult to eradicate with antibiotics.

Tracheobronchial colonization with *gram-negative bacilli* (GNB) usually precedes the onset of VAP. Risk factors for tracheobronchial colonization appear to be the same as those that favor pneumonia and include advanced age, more severe illness, longer hospitalization, prior or concomitant use of antibiotics, malnutrition, endotracheal intubation, depressed level of consciousness, immune suppression from disease or medication, azotemia, underlying pulmonary disease, and longer duration of mechanical ventilation.^{1,9,10} Experimental studies have linked some of these risk factors with changes in adherence of GNB to respiratory epithelial cells. Although formerly attributed to loss of cell surface fibronectin, these changes in adherence also reflect alterations of cell surface carbohydrates. Bacterial adhesins and prior antimicrobial therapy appear to facilitate the process. Interestingly, Enterobacteriaceae usually appear first in the oropharynx, whereas *Pseudomonas aeruginosa* more often appear first in the trachea.¹¹

Although the stomach can be a reservoir for potential pneumonia pathogens, the gastropulmonary route of infection is not the primary route of infection in most critically ill patients.¹² Progression of colonization from the stomach to the upper respiratory tract with subsequent episodes of VAP could not be demonstrated in several studies, and efforts to eliminate the gastric reservoir with antimicrobial therapy without decontaminating the oropharyngeal cavity have generally failed to prevent VAP.¹³ In fact, there is more

than one potential pathway for colonization of the oropharynx and trachea in such a setting, including cross infection from the hands of health care personnel and contaminated respiratory therapy equipment. Patient care activities, such as bathing, oral care, tracheal suctioning, enteral feeding, and tube manipulations, provide many opportunities for transmission of pathogens when meticulous infection control practices are not followed.

EPIDEMIOLOGY

INCIDENCE

The exact incidence of VAP varies widely depending on the case definition of pneumonia and the population being evaluated. For example, the incidence of VAP may be up to two times greater in patients when diagnosis is made by qualitative or semiquantitative sputum cultures rather than quantitative cultures of lower respiratory tract secretions. However, studies have confirmed that nosocomial pneumonia is considerably more frequent in ventilated patients than in other ICU patients, with the incidence being as much as 6-fold to 20-fold higher in ventilated patients than in nonventilated patients.^{14,15} VAP manifests in 9% to 27% of all intubated patients, and its incidence increases with duration of intubation.¹⁰ The risk of VAP is highest early in the course of the hospital stay—estimated to be 3% per day during the first 5 days of intubation, 2% per day during days 5 to 10 of intubation, and 1% per day after day 10.¹⁰ Because most mechanical ventilation is short term, approximately half of all episodes of VAP develop within the first 4 days of mechanical ventilation. In a large epidemiologic study, independent predictors of VAP determined by multivariate analysis were as follows: primary admitting diagnosis of burns, trauma, central nervous system disease, respiratory disease, or cardiac disease; mechanical ventilation during the preceding 24 hours; witnessed aspiration; and use of paralytic agents. Exposure to antibiotics conferred protection, but this effect was attenuated over time.¹⁰ According to four studies, the VAP rate was higher in patients with *acute respiratory distress syndrome* (ARDS) than in other ventilated patients, affecting between 34% and more than 70% of patients with ARDS and often leading to the development of sepsis, multiple organ failure, and death.¹⁶⁻¹⁹

Attributable Mortality, Morbidity, and Costs

In mechanically ventilated patients in the ICU, those with VAP appear to have a 2-fold to 10-fold higher risk of death than those without pneumonia. Although these statistics indicate that VAP can be lethal, previous studies have not clearly demonstrated that pneumonia is responsible for the higher mortality rate of these patients. It is often difficult to determine whether ICU patients with severe underlying illness would have survived if they had not developed VAP. VAP, however, has been recognized in several case-control studies or studies using multivariate analysis as an important prognostic factor for different groups of critically ill patients.²⁰⁻²⁶ Based on a multistate progressive disability model that appropriately handled VAP as a time-dependent event in a high-quality database of 2873 mechanically

ventilated patients, VAP-attributable mortality was found to be 8.1% overall.²⁷ These results are consistent with those obtained in other observational studies using also multistate model and causal analysis, detecting a relatively limited VAP-attributable mortality.^{28,29}

Other factors beyond the simple development of VAP, such as the severity of the disease, the adequacy of antimicrobial therapy, or the responsible pathogens, may be more important determinants of outcome for patients in whom pneumonia develops. Indeed, it may be that VAP increases mortality only in the subset of patients with intermediate severity of illness,²⁴ when initial treatment is inappropriate,³⁰⁻³⁴ and/or in patients with VAP caused by high-risk pathogens, such as *P. aeruginosa*.³⁵ Patients with very low severity and early-onset pneumonia caused by organisms such as *Haemophilus influenzae* or *Streptococcus pneumoniae* have excellent prognoses with or without VAP, whereas very ill patients with late-onset VAP would be unlikely to survive.

Studies have shown clearly that patients with VAP have prolonged duration of mechanical ventilation and lengthened ICU and hospital stay than do patients who do not have VAP.^{1,2} Summarizing available data, VAP appears to extend the ICU stay by at least 4 days, with the attributable ICU length of stay being longer for medical than surgical patients and for patients infected with “high-risk” rather than “low-risk” organisms.³⁶ The prolonged hospitalization of patients with VAP underscores the considerable financial burden imposed on the health care system by the development of VAP.^{37,38}

Etiologic Agents

Microorganisms responsible for VAP differ according to the population of ICU patients, the duration of hospital and ICU stays, and the specific diagnostic methods used to establish the responsible pathogens. A number of studies have shown that GNB cause many of the respiratory infections in this setting.^{1,2} The data from 24 studies conducted on ventilated patients, for whom bacteriologic studies were restricted to uncontaminated specimens, confirmed these results: GNB represented 58% of recovered organisms (Fig. 34-1). The predominant GNB were *P. aeruginosa* and *Acinetobacter* spp, followed by *Proteus* spp, *Escherichia coli*, *Klebsiella* spp, and *H. influenzae*. A relatively high rate of gram-positive pneumonias was also reported in those studies, with *Staphylococcus aureus* involved in 20% of the cases. Many episodes of VAP are caused by multiple pathogens.³⁹

Underlying diseases may predispose patients to infection with specific organisms. Patients with chronic obstructive pulmonary disease are at increased risk for *H. influenzae*, *Moraxella catarrhalis*, or *S. pneumoniae* infections; cystic fibrosis increases the risk for *P. aeruginosa* and/or *S. aureus* infections, while trauma and neurologic disease increase the risk for *S. aureus* infection. The causative agent for pneumonia also differs among ICU surgical populations, with 18% of the nosocomial pneumonias caused by *Haemophilus* spp or pneumococci, particularly in patients with trauma. *Haemophilus* spp and pneumococci are much less frequent causes of pneumonia in other surgical ICU patients, such as those with malignancy, organ transplants, or abdominal or cardiovascular surgery.^{1,2}

Despite somewhat different definitions of early-onset pneumonia, varying from onset of less than 3 to less than

Figure 34-1 Etiology of ventilator-associated pneumonia (VAP) as documented by bronchoscopic techniques in 24 studies for a total of 1689 episodes and 2490 pathogens. *Haemophilus influenzae*, *Streptococcus pneumoniae*, methicillin-sensitive *Staphylococcus aureus* (MSSA), and susceptible Enterobacteriaceae are found in early-onset VAP, whereas *Pseudomonas aeruginosa*, *Acinetobacter* spp, methicillin-resistant *S. aureus* (MRSA), and multiresistant gram-negative bacilli are more frequent in late-onset VAP. *MRSA, 56%; MSSA, 44%. †*Klebsiella* spp, 16%; *Escherichia coli*, 24%; *Proteus* spp, 22%; *Enterobacter* spp, 19%; *Serratia* spp, 12%; *Citrobacter* spp, 5%. ††Including *Corynebacterium* spp, *Moraxella* spp, and *Enterococcus* spp. (Adapted from Chastre J, Fagon JY: Ventilator-associated pneumonia. *Am J Respir Crit Care Med* 165:867–903, 2002.)

7 days, high rates of infection with *H. influenzae*, *S. pneumoniae*, methicillin-sensitive *S. aureus*, or susceptible Enterobacteriaceae were consistently found in early-onset VAP, whereas *P. aeruginosa*, *Acinetobacter* spp, methicillin-resistant *S. aureus* (MRSA), and multiresistant GNB were significantly more frequent in late-onset VAP.¹ The different pattern of distribution of etiologic agents between early- and late-onset VAP is linked to prior antimicrobial therapy in many patients with late-onset VAP. When multivariate analysis was used to identify risk factors for VAP caused by drug-resistant bacteria such as MRSA, *P. aeruginosa*, *Acinetobacter baumannii*, and/or *Stenotrophomonas maltophilia* in 135 consecutive episodes of VAP, only three variables remained significant: duration of mechanical ventilation of longer than 7 days before onset of VAP, prior antibiotic use, and prior use of broad-spectrum drugs (third-generation cephalosporins, fluoroquinolones, and/or imipenem).⁴⁰ Not all studies have confirmed this distribution pattern, and in some studies the most common pathogens associated with early-onset VAP were *P. aeruginosa*, MRSA, and *Enterobacter* spp, with similar pathogens associated with late-onset VAP.^{41,42} These findings might be explained in part by prior hospitalization and the use of antibiotics before transfer to the ICU.

Legionella spp, anaerobes, fungi, viruses, and even *Pneumocystis jirovecii* are also potential causative agents, but these microbes are not commonly found when pneumonia is acquired during mechanical ventilation. Several of these causative agents, including viruses, might be more common than reported, because they are difficult to identify.^{43,44} Iso-

lation of fungi, most frequently *Candida* species, at significant concentrations poses interpretative problems. Invasive disease has been reported in VAP, but yeasts are isolated more frequently from respiratory tract specimens in the absence of apparent disease. The use of the commonly available respiratory sampling methods (bronchoscopic or nonbronchoscopic) in ventilated patients is not sufficient to make the diagnosis of *Candida* pneumonia, and evidence of lung tissue invasion is also needed.⁴⁵

DIAGNOSIS

Two diagnostic strategies can be used when VAP is suspected, typically when a patient has new or progressive radiographic infiltrates and clinical findings suggesting infection, such as the new onset of fever, purulent sputum, leukocytosis, and a decline in arterial oxygenation. The first strategy is to treat every patient clinically suspected of having a pulmonary infection with new antibiotics, even when the likelihood of infection is low, arguing that several studies showed that immediate initiation of appropriate antibiotics was associated with reduced mortality.⁴⁶ The second strategy is to use an invasive diagnostic approach based on quantitative cultures of distal respiratory specimens obtained using bronchoscopic or nonbronchoscopic techniques, such as *bronchoalveolar lavage* (BAL) or a *protected specimen brush* (PSB), in order to improve the identification of patients with true VAP and facilitate decisions about whether or not to treat with antibiotics.^{2,47,48} Although no consensus exists on the best diagnostic strategy for patients clinically suspected of having VAP, the goal of each strategy is to institute early appropriate antibiotic therapy in patients with true VAP and to withhold it in others.^{1,2}

THE CLINICAL DIAGNOSTIC STRATEGY

With the clinical strategy, all patients suspected of having VAP are treated with new antibiotics. The selection of appropriate empirical therapy is based on risk factors and local microbiologic and resistance patterns, and involves qualitative testing to identify possible pathogens. The initial antimicrobial therapy is adjusted according to culture results or clinical response (Fig. 34-2). Antimicrobial treatment is discontinued only if the following three criteria are fulfilled on day 3: (1) clinical diagnosis of VAP is unlikely (there are no definite infiltrates found on chest radiography at follow-up and no more than one of the three following findings is present: temperature greater than 38.3° C, leukocytosis or leukopenia, and purulent tracheobronchial secretions) or an alternative noninfectious diagnosis is confirmed; (2) tracheobronchial aspirate culture results are nonsignificant; and (3) severe sepsis or shock is not present.⁴⁹

This clinical approach has two undisputable advantages: first, no specialized microbiologic techniques are required, and, second, the risk of missing a patient who needs antimicrobial treatment is minimal when all suspected patients are treated with new antibiotics.

While the simple qualitative culture of *endotracheal aspirates* (EAs) is a technique with a high percentage of

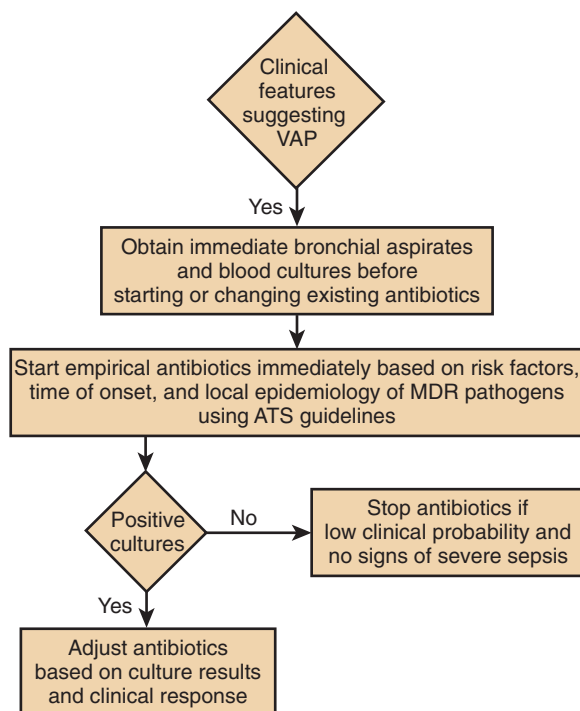

Figure 34-2 Diagnostic and therapeutic strategy applied to patients with a clinical suspicion of ventilator-associated pneumonia (VAP) managed with the “clinical” strategy. ATS, American Thoracic Society; MDR, multi-drug resistant.

false-positive results due to bacterial colonization of the proximal airways in many ICU patients, studies using quantitative culture techniques suggest that the diagnostic accuracy of EA cultures is similar to the accuracy of more invasive techniques.⁵⁰ The inherent advantages of these techniques are that they are less invasive, they are available to nonbronchoscopists, they are less expensive than bronchoscopy, they are less likely to compromise gas exchange, and they can be performed in patients with small endotracheal tubes. The disadvantages include the potential sampling errors inherent in a blind technique and lower specificity for distinguishing airway colonization from true pneumonia.

Another option when using the clinical approach is to follow the strategy described by Singh and colleagues,⁵¹ in which decisions regarding initial antibiotic therapy are based on a clinical score constructed from seven variables, the *Clinical Pulmonary Infection Score* (CPIS). Patients with a CPIS greater than 6 are considered to have VAP and are treated with antibiotics for 10 to 21 days; if the CPIS score is 6 or less, antibiotics are discontinued after 3 days (Fig. 34-3). Such an approach avoids prolonged treatment of patients who have a low likelihood of infection, while allowing immediate treatment of patients who are more likely to have VAP. Two conditions must be fulfilled when using this strategy. First, the selection of initial antimicrobial therapy should be based on the most common microbes responsible for VAP at each institution. For example, ciprofloxacin would not be the right choice in hospitals with a high prevalence of MRSA infections. Second, physicians should reevaluate antimicrobial treatment on day 3, when susceptibility patterns of the microorganisms recovered from

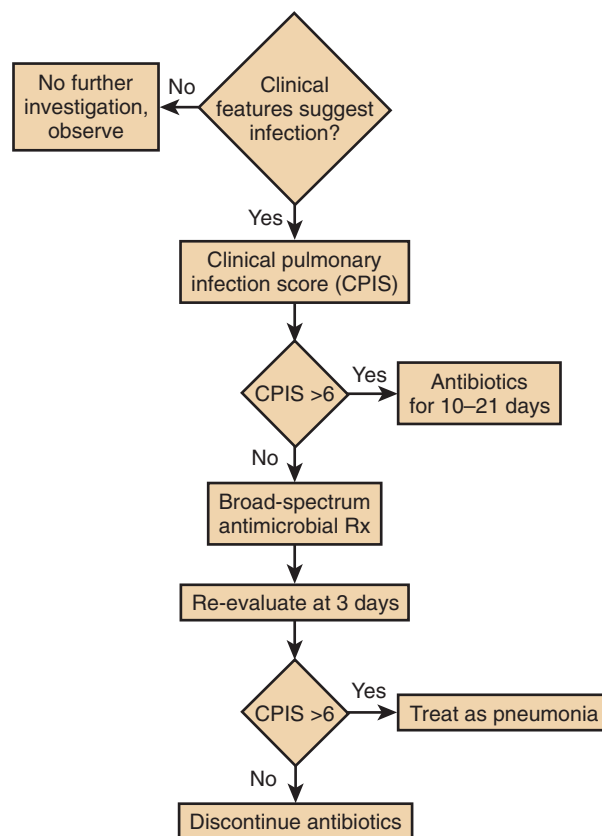

Figure 34-3 Diagnostic and therapeutic strategy applied to patients managed with a “clinical” strategy guided by a clinical pulmonary infection score (CPIS).⁵¹

pulmonary secretions are available, in order to select treatment with a narrower spectrum antibiotic.

THE INVASIVE DIAGNOSTIC STRATEGY

With the invasive strategy, quantitative cultures of lower respiratory secretions (BAL or PSB collected with or without a bronchoscope) are used to define both the presence of pneumonia and the etiologic pathogen. Growth above a threshold concentration is required to make a diagnosis of VAP and determine the causative microorganisms.⁵² Growth below the threshold is assumed to be due to colonization or contamination. Using this strategy, therapeutic decisions are made according to a strict protocol, using the results of direct examination of distal pulmonary samples and results of quantitative cultures in deciding whether to start antibiotic therapy, which pathogens are responsible for infection, which antimicrobial agents to use, and whether to continue therapy (Fig. 34-4).

Quantitative cultures of BAL and/or PSB specimens consistently yield fewer microorganisms above the diagnostic threshold than are present in qualitative cultures of tracheal aspirates.^{2,53} Thus, when therapeutic decisions are based on these data, fewer patients are treated with antibiotics and a potentially narrower spectrum of therapy is used than when using the clinical approach, thereby limiting the emergence and dissemination of drug-resistant strains and minimizing antibiotic-related toxicity.^{48,54,55}

Figure 34-4 Diagnostic and therapeutic strategy applied to patients with a clinical suspicion of ventilator-associated pneumonia managed according to the “invasive” strategy. ATS, American Thoracic Society; BAL, bronchoalveolar lavage; IDSA, Infectious Diseases Society of America; PSB, protected specimen brush.

Another compelling argument in favor of the invasive strategy is that this approach directs attention away from the lungs as the source of fever when BAL/PSB quantitative culture results are negative. Many ICU patients with negative bronchoscopic cultures have other potential sites of infection, such as the wounds, the urinary tract, or intravascular catheters, that need to be identified in order to avoid delays in initiating appropriate treatment.⁵⁶

The accuracy of bronchoscopic techniques is questionable in patients who have received prior antibiotics, particularly when new antibiotics are introduced after the onset of the symptoms suggestive of nosocomial pneumonia and before pulmonary secretions are collected. When pneumonia develops in patients who have been receiving systemic antibiotics for several days, cultures of respiratory secretions are not modified in a major way as long as the samples for culture are obtained before initiating the new antibiotics, because the bacteria responsible for the new infection are likely to be resistant to the antibiotics that were used previously.^{57,58} However, if samples for microbiologic cultures of pulmonary secretions are obtained after initiation of new antibiotics in patients suspected of having VAP, the newly initiated antibiotics can increase the number of false-negative results, regardless of the way in which the secretions are obtained.⁵⁸⁻⁶⁰

One major technical problem with all bronchoscopic techniques is proper selection of the sampling area in the tracheobronchial tree. The sampling area is usually selected based on the location of the radiographic infiltrate or on the bronchoscopic identification of a pulmonary segment that has purulent secretions.⁶¹ In patients with diffuse pulmo-

nary infiltrates or minimal new changes in a previously abnormal chest radiograph, determining the correct segment to sample can be difficult. In such cases, sampling should be directed to the area where endobronchial abnormalities are maximal. Because autopsy studies indicate that VAP frequently involves the posterior portion of the right lower lobe, this area should probably be given priority for sampling.⁶²

SUMMARY OF THE EVIDENCE

Aside from decision-analysis studies and a single retrospective study,⁶³⁻⁶⁵ five trials to date have used a randomized scheme to assess the effect of a diagnostic strategy on antibiotic use and outcome in patients suspected of having VAP.^{31,32,48,66,67} In three randomized studies conducted in Spain, no differences were found in mortality and morbidity when either invasive (PSB and/or BAL) or noninvasive (quantitative endotracheal aspirate cultures) techniques were used to diagnose VAP.^{31,32,66} These studies were relatively small, ranging from 51 to 88 patients. Antibiotics were continued in all patients despite negative cultures, thereby offsetting the potential advantage of the specific diagnostic test in patients with suspected VAP. Several prospective studies have concluded that antibiotics can be stopped in patients with negative quantitative cultures, without adversely affecting the recurrence of pneumonia and mortality.^{47,55,68,69}

In a randomized French study of 413 patients, those managed with an invasive strategy using BAL and/or PSB had a lower mortality rate on day 14, lower sepsis-related

organ failure assessment scores on day 3 and 7, and less antibiotic use.⁴⁸ Of note, in the invasive strategy group, 22 nonpulmonary infections were diagnosed, whereas in the clinical strategy group, only five were diagnosed, suggesting that physicians using the clinical strategy overdiagnosed VAP and thereby failed to identify nonpulmonary infections. A randomized trial conducted by the Canadian Critical Care Trials Group investigated the effect of different diagnostic approaches on outcomes of 740 patients suspected of having VAP.⁶⁷ There was no difference in the 28-day mortality rate in patients in whom BAL was used compared with those in whom endotracheal aspiration was used as the diagnostic strategy. The BAL group and the endotracheal aspiration group also had similar rates of targeted antibiotic therapy on day 6, days alive without antibiotics, and maximum organ dysfunction scores. Unfortunately, information about how the decision algorithms were followed in the two diagnostic arms once cultures were available was not provided, raising uncertainties about how de-escalation of antibiotic therapy was pursued in patients with negative BAL cultures. The potential benefit of using a diagnostic tool such as BAL for safely restricting unnecessary antimicrobial therapy in such a setting can be obtained only when decisions regarding antibiotics are closely linked to bacteriologic results, including both direct examination and cultures of respiratory specimens.

TREATMENT

Antimicrobial therapy of patients with VAP is a two-stage process. The first stage involves administering broad-spectrum antibiotics to avoid inadequate treatment of patients with true bacterial pneumonia.¹ The second stage focuses on trying to achieve this objective without overus-

ing or abusing antibiotics. In general, the first goal can be accomplished by identifying patients with pneumonia in a rapid fashion and starting therapy with an empirical regimen that is likely to treat the most common etiologic agents in a particular institution. This requires that the initial antibiotic choice be driven by knowledge of the likely etiologic pathogens, and the local patterns of antimicrobial resistance. The second goal involves stopping therapy in patients with a low probability of VAP, focusing and narrowing treatment once the etiologic agent is known, switching to monotherapy after day 3 whenever possible, and shortening the duration of therapy to 7 to 8 days in most patients, as determined by the patient's clinical response and information about the bacteriology (Table 34-1).

INITIAL TREATMENT

Failure to initiate prompt appropriate therapy (i.e., using an agent to which the etiologic organism is sensitive, with the optimal dose and route of administration) has been consistently linked with increased mortality in patients with VAP.^{33,46,70} Due to the emergence of multiresistant GNB, such as *P. aeruginosa*, extended-spectrum β -lactamase-producing Enterobacteriaceae, and carbapenemase-producing *Klebsiella pneumoniae*, and the increasing role of gram-positive bacteria, such as MRSA, empirical treatment with broad-spectrum antibiotics is justified in most patients with a clinical suspicion of VAP.^{2,3} The choice of agents should be based on local patterns of antimicrobial susceptibility and anticipated side effects, and should take into account the antibiotics that the patients have received within the prior 2 weeks, striving not to use the same antimicrobial classes, if possible.^{71,72} Having current knowledge about local bacteriologic patterns can increase the

Table 34-1 Proposed Strategy for Managing Antimicrobial Therapy in Patients with Ventilator-Associated Pneumonia	
Proposed Strategy	Rationale
Step 1: Start therapy using broad-spectrum antibiotics	Due to the emergence of multiresistant GNB, such as <i>P. aeruginosa</i> and ESBL-producing GNB in many institutions, and the increasing role of MRSA, empirical treatment with broad-spectrum antibiotics is justified in most patients with a clinical suspicion of VAP.
Step 2: Stop therapy if the diagnosis of infection becomes unlikely	The goal is to ensure that ICU patients with true bacterial infection receive immediate appropriate treatment. However, this can result in more patients receiving antimicrobial therapy than necessary, because clinical signs of infection are nonspecific.
Step 3: Use narrower spectrum antibiotics once the etiologic agent is identified	For many patients with VAP, including those with late-onset infection, therapy can be narrowed once the results of respiratory tract and blood cultures are available, either because an anticipated organism (e.g., <i>P. aeruginosa</i> and <i>Acinetobacter</i> spp. or MRSA) was not recovered, or because the organism isolated is sensitive to a more narrow-spectrum antibiotic than used in the initial regimen.*
Step 4: Use pharmacokinetic-pharmacodynamic data to optimize treatment	Clinical and bacteriologic outcomes can be improved by optimizing the therapeutic regimen according to pharmacokinetic and pharmacodynamic properties of the agents selected for treatment.
Step 5: Switch to monotherapy on days 3 to 5	There are no clinical benefits to using a regimen combining two antibiotics for more than days 3 to 5, provided that initial therapy was appropriate, the clinical course appears favorable, and microbiologic data do not point to a very difficult-to-treat microorganism.
Step 6: Shorten the duration of therapy	Reducing duration of therapy in patients with VAP has led to good outcomes with less antibiotic use. Prolonged therapy leads to colonization with antibiotic-resistant bacteria, which may precede a recurrent episode of VAP.

likelihood that appropriate initial antibiotic treatment will be prescribed.^{73,73a} Only patients with early-onset infection and no specific risk factors, such as prolonged duration of hospitalization, admission from a health care–related facility, and recent prolonged antibiotic therapy, can be treated with a relatively narrow-spectrum drug, such as a nonpseudomonal third-generation cephalosporin.¹

Several published reports have demonstrated the need to adjust the target dose of antimicrobial agents used in treating severe VAP to the individual patient's pharmacokinetics and the putative bacterial pathogens' susceptibilities.^{74–83c} Most investigators distinguish between antimicrobial agents that kill by a concentration-dependent mechanism (e.g., aminoglycosides and fluoroquinolones) from those that kill by a time-dependent mechanism (e.g., β -lactams and vancomycin). Altered pharmacokinetics secondary to an increase in the volume of distribution in critically ill patients can result in insufficient serum β -lactam concentrations when standard doses are administered, emphasizing the need to monitor peak and trough levels of antibiotics carefully when treating resistant pathogens.^{83,84} Higher dosing regimens than those usually recommended and/or prolonged duration of infusion are frequently needed in such circumstances. Development of a priori dosing algorithms based on minimal inhibitory concentrations, patient creatinine clearance and weight, and the clinician-specified area under the inhibitory curve target might be a valid way to improve treatment of these patients, leading to a more precise approach than current guidelines for use of antimicrobial agents.

AVOIDING THE OVERUSE OF ANTIBIOTICS

The need to ensure that ICU patients with true bacterial infections promptly receive an appropriate antibiotic regimen can lead to many more patients receiving antimicrobial therapy than is actually necessary, because clinical signs of infection are relatively nonspecific. Thus, when a clinical approach to VAP is used, it is important to perform serial clinical and microbiologic evaluations, and to reevaluate therapy after 48 to 72 hours so that it can be stopped if infection is unlikely. To accomplish this, all diagnostic strategies that are designed for managing patients with a clinical suspicion of VAP should make explicit the decision tree that is used to identify patients with a low probability of infection, in whom therapy can be stopped when infection appears improbable.

For many patients with VAP, including those with late-onset infection, therapy can be narrowed once the results of respiratory tract and blood cultures are available, if no resistant organism (e.g., *P. aeruginosa*, *Acinetobacter* spp or MRSA) is recovered or if the isolated organism is sensitive to a narrower spectrum antibiotic. For example, vancomycin and linezolid should be stopped if MRSA is not identified, unless the patient is allergic to β -lactams or has developed an infection caused by a gram-positive microorganism. Very-broad-spectrum agents, such as carbapenems, piperacillin-tazobactam, and/or cefepime, should also be restricted to patients with infection caused by pathogens that are only susceptible to these agents. Clinicians must be aware that the emergence of resistant variants may lead to treatment failure when third-generation cephalosporins

are chosen to treat infections caused by *Enterobacter*, *Citrobacter*, *Morganella morganii*, indole-positive *Proteus*, and *Serratia* spp, due to the presence of inducible β -lactamases, even if the isolate is initially characterized as susceptible.

The most common reason to use combination therapy in initial management of patients with VAP is to achieve synergy in treating *P. aeruginosa* or other difficult-to-treat GNB. However, antibiotic synergy has been shown to be valuable only in vitro and in patients with neutropenia⁸⁵ or bacteremic infection,⁸⁶ which is uncommon in VAP. A recent meta-analysis evaluated all prospective randomized trials of β -lactam monotherapy compared with β -lactam/aminoglycoside combination regimens in 7586 patients with sepsis, of whom at least 1200 patients had VAP.⁸⁷ The clinical success rates were similar with monotherapy versus combination therapy, and combination therapy had no advantage in the treatment of *P. aeruginosa* infections. Importantly, combination therapy did not prevent the emergence of antimicrobial resistance during treatment, but it was associated with a significantly higher rate of nephrotoxicity. Based on these data, therapy can be switched to monotherapy in most patients after 3 or 5 days, as long as initial therapy is appropriate, the clinical course is favorable, and microbiologic data do not identify a difficult-to-treat microorganism with a high in vitro minimal inhibitory concentration, as is found with some lactose-nonfermenting GNB.

Efforts to reduce the duration of therapy for VAP are justified by studies of the natural history of the response to therapy. Most patients with VAP who receive appropriate antimicrobial therapy have a good clinical response within the first 6 days.^{88–90} Prolonged therapy promotes colonization with antibiotic-resistant bacteria, which may lead to a recurrent episode of VAP. A multicenter randomized controlled trial of 401 patients with microbiologically proven VAP showed that the clinical outcomes of patients who received appropriate empirical therapy for 8 days were similar to those of patients who received therapy for 15 days.⁹¹ A trend to greater rates of relapse for short-duration therapy was seen when the etiologic agent was *P. aeruginosa* or *Acinetobacter* spp, but the clinical outcomes were indistinguishable. These results were confirmed in two later studies, including a prospective randomized trial of 290 patients evaluating an antibiotic discontinuation policy.^{92,93} Possible exceptions to this recommendation include immunosuppressed patients, those whose initial antimicrobial treatment was not appropriate for the causative microorganisms, and patients whose infection was caused by nonfermenting GNB and had no improvement in clinical signs of infection.

Many clinicians remain hesitant about prescribing antibiotics for fewer days for patients with VAP, and they prefer to customize antibiotic duration based on the clinical course of the disease and/or using serial determinations of a biomarker such as procalcitonin. The rationale for using a biomarker to tailor antibiotic treatment duration relies on evidence that the inflammatory response is often proportional to infection severity. When that response is absent or low, it might be logical to discontinue antibiotics earlier. Thus, adapting antimicrobial treatment duration to procalcitonin kinetics seems reasonable and has been demonstrated as useful in several randomized trials targeting

patients with acute respiratory infection, including five trials conducted in the ICU.⁹⁴⁻¹⁰⁰

AEROSOLIZED THERAPY

Because insufficient delivery of antibiotics to the site of infection in patients with VAP may lead to clinical and microbiologic failures, efforts to increase pulmonary delivery of antimicrobial agents have been investigated. Delivering drugs via aerosolization is one approach, assuming that this technique actually promotes higher drug concentrations at the infected site. By achieving high pulmonary antibiotic concentrations, this mode of administration could increase the antibacterial activity of concentration-dependent antibiotics, such as aminoglycosides, or provide bactericidal activity of antibiotics in infections caused by pathogens of impaired sensitivity. By limiting systemic exposure, it could also allow the administration of antibiotics with high systemic toxicity, such as aminoglycosides and polymyxins.

Several studies, based on nebulizers with improved technology, have renewed the interest in aerosolized antibiotic therapy for VAP.¹⁰¹⁻¹⁰⁴ In anesthetized piglets on mechanical ventilation for severe *E. coli* bronchopneumonia, amikacin lung tissue concentrations were markedly higher following aerosolization as compared to intravenous administration.¹⁰⁵ In a study using a device with a vibrating plate and multiple apertures to produce an aerosol of amikacin, the nebulized drug was well-distributed in the lung parenchyma, with high tracheal and alveolar levels and serum concentrations below the renal toxicity threshold.¹⁰⁶ Aerosolized amikacin was well-tolerated, without any severe adverse event, and patients who received amikacin twice daily required significantly fewer other antibiotics than patients given placebo.¹⁰⁷

Aerosolized polymyxin is also being used to treat infections caused by multidrug-resistant GNB, mainly *Acinetobacter baumannii*, *P. aeruginosa*, and carbapenemase-producing *K. pneumoniae*, with mixed results.^{103,104,108,109} In a randomized trial of 100 patients with VAP due to GNB (predominantly multi-drug resistant *A. baumannii* and/or *P. aeruginosa*), patients treated with a combination of systemic antibiotics and nebulized colistin had a higher rate of favorable microbiologic outcome compared with patients treated with systemic antibiotics alone (microbiologic eradication or presumed eradication 61% vs. 38%), but there were no differences in the rate of favorable clinical outcomes (51% vs. 53%).¹⁰⁴ In a retrospective case-control study of 86 patients with VAP due to multidrug-resistant GNB (predominantly *A. baumannii*) treated with a combination of intravenous and aerosolized colistin compared with intravenous colistin alone, there was only a trend toward improved rates of clinical cure, pathogen eradication, and mortality in the patients who received aerosolized and intravenous colistin.¹⁰³

Thus, although recent investigations emphasize the potential contribution of aerosolized antibiotics to treat VAP as an adjunctive therapy to intravenous antibiotics, the clinical impact of such a strategy has not been established. At present, aerosolized antibiotics can only be recommended to treat patients with multidrug-resistant VAP for which no effective intravenous antibiotics are available.

Large prospective trials are needed to evaluate the potential usefulness of this therapeutic modality.

PREVENTION

Because VAP is associated with increased morbidity, longer hospital stay, increased health care costs, and higher mortality rates, prevention is an important goal.^{1,110,111}

CONVENTIONAL INFECTION CONTROL APPROACHES

The design of the ICU has a direct effect on the potential for nosocomial infections. Adequate space and lighting, properly functioning ventilation systems, and appropriate handwashing facilities all lead to lower infection rates.¹¹² It is important to note, however, that upgrading the physical environment does not reduce the infection rate unless the attitudes and practices of health care personnel are also improved. In any ICU, one of the most important factors is the health care staff, including the number, quality, and motivation of medical, nursing, and ancillary members. The team should include a sufficient number of nurses to minimize their movement from one patient to another and to avoid having them work under constant pressure.¹¹³⁻¹¹⁶ The importance of personal cleanliness and attention to aseptic procedures must be emphasized at every opportunity. It is clear that careful monitoring, decontamination, and compliance with guidelines for the use of respiratory equipment all reduce the incidence of nosocomial pneumonia.¹¹⁷ Handwashing and hand rubbing with alcohol-based solutions remain the most important components of effective infection control practices in the ICU.^{118,119}

Environmental and patient-oriented microbiologic monitoring facilitates the early recognition of colonization and infection, and has been associated with significant reductions in nosocomial infection rates.¹²⁰ The focal point for infection control activities in the ICU is a surveillance system designed to establish and maintain a database that identifies endemic rates of nosocomial infections. This information facilitates the recognition of epidemics, when infection rates rise above the endemic threshold for a specific type of nosocomial infection.

An antibiotic policy that restricts the prescription of broad-spectrum agents and inappropriate antibiotics is of major importance. Better use of antibiotics in the ICU can be achieved by implementing strict guidelines, avoiding the treatment of patients who do not have bacterial infections, using narrow-spectrum antibiotics whenever possible, and reducing the duration of treatment.^{121,122} Similarly, transfusion of red blood cells and other allogenic blood products should follow a strict policy, because several studies have identified exposure to allogenic blood products as a risk factor for postoperative infection and pneumonia.^{123,124}

SPECIFIC PROPHYLAXIS AGAINST VENTILATOR-ASSOCIATED PNEUMONIA

Specific strategies aimed at reducing the duration of mechanical ventilation (a major risk factor for VAP), such as improved methods of sedation,¹²⁵ use of protocols to

facilitate and accelerate weaning,¹²⁵⁻¹²⁷ using adequate levels of positive end-expiratory pressure,¹²⁸ and using intensive insulin therapy to control blood glucose¹²⁹ are integral parts of any infection control program. All are based on the application of strict protocols. Similarly, non-invasive positive-pressure ventilation using a face mask should be employed whenever possible.¹³⁰

Some very simple, safe, inexpensive, and logical measures may have major effects on the frequency of VAP in mechanically ventilated patients.^{1,119} These include avoiding nasal insertion of endotracheal and gastric tubes,¹³¹ maintaining the endotracheal tube cuff pressure above 20 cm H₂O to prevent leakage of bacteria around the cuff into the lower respiratory tract,^{132,133} promptly reintubating patients who are likely to fail extubation,¹³⁴ keeping patients in the semirecumbent position, especially when enteral nutrition is used,¹³⁵ removing tubing condensate,¹³⁶ and providing adequate oral hygiene with an antiseptic such as chlorhexidine.¹³⁷⁻¹³⁹

Continuous or intermittent suctioning of oropharyngeal secretions has been proposed as a means to avoid chronic aspiration of secretions through the tracheal cuff of intubated patients. Aspiration of subglottic secretions requires the use of a specially designed endotracheal tube with a separate lumen that opens into the subglottic region. Thirteen randomized controlled trials with a total of 2442 randomized patients have studied aspiration of subglottic secretions for the prevention of VAP.¹⁴⁰⁻¹⁴⁸ Of the 13 studies, 12 reported a reduction in VAP rates in the subglottic secretion drainage arm. When the results were combined in a meta-analysis, the overall risk ratio for VAP was 0.55 (95% CI, 0.46-0.66; $P < 0.00001$) with no heterogeneity, and the use of subglottic secretion drainage was associated with reduced ICU length of stay, decreased duration of mechanical ventilation, and increased time to first episode of VAP.¹⁴⁸ However, there was no effect on hospital or ICU mortality.¹⁴⁸ Preliminary data in animal models and from small randomized human studies support the hypothesis that an endotracheal tube coated externally and internally with a potent antiseptic product such as silver could have a sustained antimicrobial effect within the proximal airways and block biofilm formation at its surface.¹⁴⁹⁻¹⁵⁴ Such a device was evaluated in a large, randomized, multicenter, single-blind trial.¹⁵⁵ The authors conclude that the new device was able to lower the VAP frequency from 7.5% for the control group to 4.8% for the group receiving the silver-coated endotracheal tube. The silver-coated tube, however, did not reduce mortality rates, the duration of intubation, hospital length of stay, or the frequency or severity of adverse effects.

Gastric colonization by potentially pathogenic organisms increases with decreasing gastric acidity.¹⁵⁶ Thus, medications that decrease gastric acidity (antacids, *histamine*₂ [H₂] blockers) can increase the gastric bacterial burden and increase the risk of VAP; medications that do not affect gastric acidity (e.g., sucralfate) do not appear to increase this risk. Several meta-analyses of more than 20 randomized trials have evaluated the risk for VAP associated with methods used to prevent gastrointestinal bleeding in critically ill patients.¹⁵⁷ The largest randomized trial comparing ranitidine to sucralfate showed that ranitidine was superior in preventing gastrointestinal bleeding and did not increase the risk of VAP.¹⁵⁸ Therefore, despite the potential advantage

of sucralfate (potentially less VAP with more gastrointestinal bleeding) over H₂ blockers (potentially more VAP with less gastrointestinal bleeding) in preventing VAP, stress ulcer prophylaxis with H₂ blockers appears to be safe in patients who are at high risk for bleeding as well as VAP. Although proton-pump inhibitors are now widely used for gastric bleeding prophylaxis in the ICU, based on their potentially higher efficacy, their use is associated with similar rates of nosocomial pneumonia as H₂ blockers.¹⁵⁹⁻¹⁶⁴

Selective decontamination of the digestive tract (SDD) includes a short course of systemic antibiotic therapy, such as cefotaxime, trimethoprim or a fluoroquinolone, and topical administration of nonabsorbable antibiotics (usually an aminoglycoside, polymyxin B, and amphotericin) to the mouth and stomach, in order to eradicate potentially pathogenic bacteria and yeast that may cause infections.¹⁶⁵ Since the original study published by Stoutenbeek and coworkers in 1984,¹⁶⁶ which demonstrated a decrease of the overall infection rate in patients receiving the SDD regimen, more than 40 randomized controlled trials and eight meta-analyses have been published. All eight meta-analyses reported a significant reduction in the risk of VAP, and four reported a significant reduction in mortality.¹⁶⁷⁻¹⁷¹ Recently, three prospective, randomized, controlled trials, all performed in ICUs with low rates of antibiotic resistance, have been published that were large enough to show a significant survival benefit in SDD-treated patients.¹⁷²⁻¹⁷⁴ All three were in favor of treatment with SDD, the largest and most recent one demonstrating a relative decrease in 28-day mortality rate (OR 0.83, 95% CI, 0.72 to 0.97) and an absolute survival benefit of 3.5%.¹⁷⁴ Even so, widespread use of SDD in ICU patients remains controversial. The major concern with use of SDD is that it can promote the emergence of resistant bacteria, particularly gram-positive bacteria such as MRSA.¹⁷⁵⁻¹⁷⁹ This is likely to be even a greater problem in ICUs with a high baseline rate of resistance.^{110,111,180} In contrast to what was expected, however, most studies that have evaluated this issue showed a lower incidence of colonization with resistant bacteria in SDD-treated patients than in control patients.^{173,181-184} Putative explanations why colonization with resistant microorganisms is lower after treatment with SDD include the susceptibility of gram-negative aerobic bacteria to the commonly used combination of polymyxin E and tobramycin, the fact that treatment with polymyxin E rarely induces resistance, the very high local concentrations in the bowel of the used antibiotics, and the lower rate of use of systemic antibiotics in SDD-treated patients.¹⁸⁵

IMPLEMENTING A STRUCTURED PREVENTION POLICY

The application of consistent evidence-based interventions to prevent VAP has been highly variable from one ICU to another and is often suboptimal. Furthermore, no single preventive measure can succeed alone, emphasizing the need to use multifaceted and multidisciplinary programs to prevent VAP. Such programs are frequently referred to as "care bundles." A care bundle is a set of readily implementable interventions that are required to be undertaken for each patient on a regular basis.¹⁸⁶ The key goal is for every intervention to be implemented for every patient on

every day of his or her stay in the ICU. Compliance is assessed for the bundle as a whole, so failure to complete even a single intervention means failure of the whole bundle at a particular assessment. The interventions need to be packaged in such a way that compliance is readily assessed, which usually means that no more than five interventions are included in each care bundle. The performance goal is to routinely achieve over 95% compliance. Care bundles make it possible to introduce evidence-based preventive measures, including appropriate nurse staffing levels, hand hygiene with alcohol-based formulations, standardized weaning protocols and daily interruption of sedation, oral care with chlorhexidine, and keeping patients who receive enteral nutrition in a semirecumbent position.¹⁸⁷ Several studies using quasiexperimental design have confirmed the usefulness of this strategy for preventing VAP in the ICU.¹⁸⁸⁻²⁰²

The lack of methodologic rigor of the reported studies, however, precludes any conclusive statements about “bundle care” effectiveness or cost-effectiveness. The exact set of key interventions that should be part of the “VAP-prevention bundle” is also not currently known, nor are factors contributing to its success.^{199,203-205b} Successful VAP prevention requires an interdisciplinary team, educational interventions, system innovations, process indicator evaluation, and feedback to health care workers. As shown in a recent study, simply having a checklist available for reference without consideration of a robust implementation and adherence strategy is unlikely to maximize patient outcomes.²⁰²

In the United States, the Centers for Medicare and Medicaid Services has proposed stopping hospital reimbursements for care made necessary by preventable complications, including nosocomial infections, aiming for a zero-VAP rate.²⁰⁶ Although this plan may have the desirable consequences of improving the quality of care, it also may penalize hospitals that admit high-risk patients and inadvertently encourage institutions to underreport VAP or to overuse antibiotics, thereby favoring dissemination of multidrug-resistant microorganisms. This possibility further underscores the need to evaluate all new strategies potentially aimed at preventing VAP against current best clinical practices.

Key Points

- Ventilator-associated pneumonia (VAP) is associated with mortality in excess of that caused by the underlying disease alone, particularly in the case of infection due to high-risk pathogens, such as *P. aeruginosa* and methicillin-resistant *S. aureus*, and/or when the initial therapy is inappropriate.
- The predominant organisms responsible for infection are *P. aeruginosa*, *S. aureus*, and Enterobacteriaceae, but etiologic agents widely differ according to the population of hospital patients, the duration of hospital stay, and prior antimicrobial therapy.
- Because even a few doses of a new antimicrobial agent can negate results of microbiologic cultures, pulmonary

secretions in patients suspected of having developed VAP should always be obtained before new antibiotics are administered.

- The initial approach to antimicrobial therapy involves administering broad-spectrum antibiotics to avoid inadequate treatment in patients with true bacterial pneumonia.
- The management of antibiotic therapy for VAP should optimize care without overusing and abusing antibiotics by stopping therapy in patients with a low probability of VAP, streamlining treatment once the etiologic agent is known, switching to monotherapy after days 3 to 5, and shortening duration of therapy to 7 to 8 days, as dictated by the patient’s clinical response to therapy and information about the bacteriology of the infection.
- Very simple, no-cost measures can have an important effect on decreasing the frequency of VAP: maintaining the endotracheal tube cuff pressure above 20 cm H₂O to prevent leakage of bacteria around the cuff into the lower respiratory tract; promptly reintubating patients who are failing extubation; providing oral care with chlorhexidine; keeping patients in the semirecumbent position, especially patients receiving enteral nutrition; removing ventilator tubing condensates with minimal exposure to patients; and reducing the duration of ventilation.

Mycobacteria have played an extremely important role in influencing society throughout history. Tuberculosis and Hansen disease (leprosy), the two most prominent mycobacterial diseases, have been recognized as scourges of humanity since antiquity. Whereas leprosy was most apparent as a metaphor for the destitute, disabled, and disfigured, tuberculosis was the “captain of all these men of death,” according to John Bunyan—a plague that carried away the young and talented members of society. Currently, although the resurgence of tuberculosis in industrialized countries that began in the mid-1980s has subsided, the disease continues to ravage much of the developing world and to kill or disable many young, productive members of society.^{1,2}

Because pulmonary and extrapulmonary tuberculosis commonly appear together, and because the general manifestations and microbiologic features are the same with all sites of disease, this chapter addresses both pulmonary and extrapulmonary tuberculosis.

Some forms of extrapulmonary tuberculosis, such as genitourinary, bone and joint, central nervous system, abdominal, and pericardial tuberculosis are covered in the online version of this chapter, which can be found at ExpertConsult.

Because tuberculous infection is so prevalent throughout much of the developing world, the conflicts and upheavals that result in immigration from low-income to developed countries will have a continuing influence on the incidence of tuberculosis everywhere. For this reason, tuberculosis

must be viewed as a global problem, one that is not contained by national boundaries and whose effects are felt in all countries regardless of their state of development.³ In addition to *human immunodeficiency virus* (HIV) infection, drug resistance is providing increasing challenges to tuberculosis control efforts.⁴ Both *multidrug-resistant* (MDR) tuberculosis (caused by organisms resistant to at least isoniazid and rifampin) and *extensively drug-resistant* (XDR) tuberculosis (caused by MDR organisms that are also resistant to one of the fluoroquinolones and to at least one injectable second-line agent) pose significant difficulties for tuberculosis control programs in most of the world.

**CHARACTERISTICS OF THE
MYCOBACTERIUM TUBERCULOSIS
COMPLEX ORGANISMS**

The main phenotypic characteristic that defines the genus *Mycobacterium* is the property of “acid-fastness,” the ability to withstand decolorization with an acid-alcohol mixture after coloration with such stains as carbol fuchsin or auramine O (Fig. 35-1).⁵ In addition to being acid fast, the mycobacteria are primarily intracellular pathogens, are obligate aerobes, and, in the presence of a normal immune response, induce a granulomatous response in tissue. Most members of the genus that cause disease in immunocompetent humans are phylogenetically close and possess genes that encode the virulence factors ESAT-6 and CFP-10 (see “ESX-1 Protein Secretion System” later).⁶

Tuberculosis is caused by any one of three mycobacterial pathogens that are part of the *M. tuberculosis* complex: *M. tuberculosis*, *Mycobacterium bovis*, and *Mycobacterium africanum*. The other members of the *M. tuberculosis* complex are: *Mycobacterium microti*, *Mycobacterium pinnipedii*, and *Mycobacterium caprae*, which only rarely cause disease in humans. *Mycobacterium magerit*⁷ and *Mycobacterium oryzi*⁸ have not been reported to cause disease in humans. *M. africanum* causes disease that is clinically indistinguishable from that of *M. tuberculosis*, but it is restricted to specific regions of Africa or people from those regions. *Mycobacterium canettii* is not part of the *M. tuberculosis* complex, but it has been identified as a cause of tuberculosis in a small number of patients from or with connection to East Africa.⁹ This strain diverged from the common ancestor of all tubercle bacilli much earlier than the *M. tuberculosis* complex.

Since the publication of the first complete genome of *M. tuberculosis* H37Rv laboratory strain,¹⁰ multiple clinical isolates have been sequenced and are publicly available in GenBank¹¹ and the Tuberculosis Database (TBDB; www.tbdb.org). The sequence of H37Rv genome is annotated and frequently revised and updated (<http://tuberculist.epfl.ch/>). The most recent version of the H37Rv annotation (R27-March 2013) included 4018 protein coding genes, of which 88% have a defined or possible function and the rest are annotated as conserved hypothetical proteins without known function.¹² The genome of *M. tuberculosis* differs from other bacterial genomes in that 6% of the genes are predicted or known to be involved in lipid biosynthesis and degradation.¹¹ Nearly 400 of its putative proteins share no homology with known proteins and, thus, could be unique to *M. tuberculosis*.¹³ The genetic makeup of the organism indicates that it has the potential to survive in a variety of environments, including those with low oxygen tension.

The potential for developing new drugs, vaccines, and diagnostic tests on the basis of the knowledge of the complete array of genes in *M. tuberculosis* is enormous and is only beginning to be realized. For example, the analysis of the whole genome sequence of 21 *M. tuberculosis* clinical isolates representative of the global bacterial population showed that human T-cell epitopes (peptide fragments in *M. tuberculosis* used by T-cell lymphocytes to recognize the

pathogen) were surprisingly highly conserved, in contrast to the situation with other pathogens in which antigens undergo a high frequency of variation.¹⁴ These results indicate that *M. tuberculosis* does not use antigenic variation as a major mechanism of immune evasion, and the results may help guide vaccine development.

In addition to providing information about the biology of *M. tuberculosis*, the analysis and comparison of whole genome sequences have provided phylogenetically robust markers that enable assessment of the evolution and classification of clinical isolates of *M. tuberculosis*, as well as provide tools to examine the impact of genetic diversity on the epidemiology and clinical features of tuberculosis.¹⁵

The *M. tuberculosis* phylogenetic tree has a geographic structure from which the initial *M. tuberculosis* major lineage names were derived: Indo-Oceanic (lineage 1), East-Asian (lineage 2), Indian and East-African (lineage 3), Euro-American (lineage 4), West-African 1 (lineage 5), and West-African 2 (lineage 6). These last two lineages are also known as *M. africanum*.¹⁵ This classification has been confirmed using large-sequence polymorphisms (insertions and deletions), multilocus sequence analysis, and genome sequencing, which is now the gold standard for phylogeny studies.¹⁶ Several studies have suggested that different lineages of *M. tuberculosis* may be associated with different degrees of pathogenicity.¹⁷⁻²¹ In The Gambia, the rate of transmission (measured by skin test conversion) of *M. tuberculosis* to household contacts was similar among different lineages. However, the proportion of contacts developing active tuberculosis within the 2-year follow-up period varied: 1% for those exposed to strains of *M. africanum*, 6% for those exposed to strains from lineage 2, and 1% to 4% for strains from lineage 4.²⁰ In San Francisco, strains from sublineage 207, a sublineage of lineage 2, were more likely to be associated with genotypic clustering (a measurement of the ability of a strain to cause secondary cases) and were more virulent in guinea pigs when compared with the other lineage 2 sublineages.^{22,23} Similarly, strains from sublineage 183, within lineage 4, caused more secondary cases compared with other lineage 4 sublineages.²⁴ In California, MDR *M. tuberculosis* caused by lineage 2 organisms was associated with genotypic clustering, whereas lineage 1 strains produced no secondary (clustered) cases.²⁵

DESCRIPTIVE EPIDEMIOLOGY OF TUBERCULOSIS

For most of recorded history, tuberculosis has been a problem of enormous dimensions worldwide—and it still is. The *World Health Organization* (WHO) estimates that nearly one third (1.9 billion people) of all the people in the world are infected with *M. tuberculosis*. According to the latest (2013) WHO Global report, in 2012 there were an estimated 8.6 million new cases, of which only 6.1 million were reported to national tuberculosis programs, leaving an estimated 2.5 million unaccounted for.² This gap is likely related to limitations in the global surveillance and reporting systems and because a large amount of care is delivered by the private sector with no reporting. The total number of prevalent cases (new and existing) in the world was estimated to be 12 million, from which there were an estimated 1.26 million deaths, making tuberculosis the eighth most common cause of death in low-income countries.²⁶ Most of the persons with tuberculosis (>95%) and nearly all of those who die from it (98%) reside in low- and middle-income countries.

Since 1990, there has been a progressive decrease in the incidence of tuberculosis in all nine WHO regions of the world, although the rates of decline in Eastern Europe and Africa lag behind other regions.² Globally the rate of decline in incidence is about 2% per year, although this rate varies from region to region. Also, in 2012, it was estimated that there were 1.1 million new cases and 300,000 deaths from tuberculosis in persons with HIV infection. The distribution of persons with coexisting HIV and tuberculosis varies considerably around the world, but most (79%) live in sub-Saharan Africa.

In spite of the staggering impact of tuberculosis in developing countries, it was believed that the disease was well on its way to being eliminated in most of the high-income, low-incidence countries, including the United States. In these high-income countries, from at least the beginning of the 20th century, tuberculosis death rates were steadily decreasing, a decline that was accelerated by the introduction of antituberculosis chemotherapy in the late 1940s. In the United States following the introduction of effective chemotherapy, rates of new cases of tuberculosis decreased steadily at an average annual rate of approximately 5%. However, between 1984 to 1992, the number of tuberculosis cases increased by 20%. With renewed effort and considerably increased funding, case rates once again began to decline in 1993, as shown in [Figure 35-2](#).

In 2012 in the United States, 9945 cases of tuberculosis (3.2 cases per 100,000 population) were reported, the lowest number since systematic national reporting began in 1953, and a 5.4% decline from 2011.²⁷ The reasons for the resurgence of tuberculosis in the late 1980s and early 1990s in the United States, as well as in Western Europe, are complex but revolve largely around two major factors: the epidemic of infection with HIV and the deterioration of public health systems.^{28,29} Interacting with and amplifying these two major factors were two additional circumstances: (1) socioeconomic conditions, particularly homelessness that led to crowding; and (2) immigration of persons from

Figure 35-2 Cases of tuberculosis reported per year in the United States, 1953–2013. (From Centers for Disease Control and Prevention: Reported tuberculosis in the United States, 2013. Atlanta, 2014.)

countries in the world where the prevalence of tuberculous infection was high.

Whereas the incidence of tuberculosis decreased overall by 81% from 1993 to 2012, the incidence decreased disproportionately among the U.S.-born population.²⁷ There was a 53% reduction in incidence among the foreign born during the same time period; however, the rate remains relatively high at 15.9/100,000. Among foreign-born persons, rates of tuberculosis are the highest during the first 2 years after entry into the country, regardless of age, with annual rates especially high (>250/100,000 persons) among immigrants from sub-Saharan Africa and Southeast Asia.³ By contrast, in the United States and other low-incidence countries, tuberculosis case rates in persons born in these countries tend to be higher in older individuals, because the older a person is, the more likely he or she is to have acquired tuberculous infection, having lived during a time when the disease was more prevalent than it is today.

TRANSMISSION OF MYCOBACTERIUM TUBERCULOSIS

Knowledge of the factors that govern transmission of *M. tuberculosis* from a source case and of the sequence by which the disease develops in a potential new host is vital for devising strategies for tuberculosis control and for evaluating the risk of a person becoming infected after exposure to a patient with tuberculosis.³⁰

Transmission of *M. tuberculosis* is influenced by features of the source case, particularly the bacillary load, by the closeness of the potential recipient of the organism to the source, and by the condition of the environmental air they share. A possible additional factor is the infectivity of the organism—the degree to which *M. tuberculosis* has the ability to establish itself within the lung or other sites in the new host. However, even taking these factors into account,

there is substantial unexplained variability in the degree to which persons with untreated tuberculosis transmit the infection to persons to whom they are exposed.

SOURCE CASE

Transmission of *M. tuberculosis* is a classic example of an airborne infection.³¹ In nearly all instances, tuberculous infection is acquired by inhalation of one or more tubercle bacilli contained in an airborne particle small enough (1 to 5 μm) to reach an alveolus. For a person with tuberculosis to be infectious, the organisms must have access to environmental air and be aerosolized. By and large, this means that only patients with pulmonary tuberculosis can be regarded as infectious. However, respirable particles containing *M. tuberculosis* may rarely be generated from other sources (e.g., irrigation of a tuberculous abscess).³² After aerosolized respiratory secretions are expelled from the nose or mouth, their water content evaporates rapidly, leaving only a small residue of solid matter—the *droplet nucleus*—which may include tubercle bacilli and which may remain suspended in the air for several hours.³³ A single bacillus in a tiny droplet nucleus is more hazardous than several bacilli in larger airborne particles, which when inhaled deposit in airways rather than alveoli and which then are quickly removed by mucociliary clearance or killed.

Coughing is the most effective mechanism for generating aerosols that create droplet nuclei, but it is not the only mechanism. Forced expiratory maneuvers other than coughing—such as sneezing, yelling, singing, and loud talking—all involve, to a greater or lesser extent, the sudden acceleration of air required to disrupt a liquid surface or mucous strands, thereby aerosolizing particles. Thin, watery secretions are more easily fragmented into small respirable droplets than is more viscous mucus. In general, the greater the volume of respiratory secretions, the greater the number of potentially infectious droplets. Riley and coworkers³⁴ demonstrated marked variability in the infectious potential of tuberculosis patients that, in part, could be related to the severity of coughing. One patient with exceptionally infectious tuberculosis not only had severe pulmonary tuberculosis but tuberculous laryngitis as well. It was calculated that this patient was as contagious as a child with measles is to other susceptible children. Similar studies by Escombe and coworkers,³⁵ which described the infectiousness of HIV-infected patients with tuberculosis, reported that infectiousness was very heterogeneous. Of 97 patients (118 admissions) hospitalized in an HIV-tuberculosis ward, 10 caused 90% of the infections in guinea pigs exposed to air exhausted from the ward. Of the 10 infectious patients, 6 had MDR tuberculosis that was inadequately treated; in addition to having MDR tuberculosis, being sputum smear positive and being on suboptimal treatment both contributed to the degree of infectiousness. Likewise, in a study of household contacts of tuberculosis patients, the likelihood of transmission was lower if the source case was HIV infected and had a CD4 T-cell count lower than 250/ μL .³⁶ In that study, the effect of HIV and immunodeficiency was larger than could be explained by differences in smear status, delayed treatment, or the presence of cavitory lesions. Even when the bacillary load is taken into account, there is substantial unexplained

variability in infectiousness. Jones-Lopez and colleagues³⁷ used an air-sampling device to capture *M. tuberculosis* in exhaled (coughed) air and showed that infectiousness was associated with the presence of cultivable organisms in the sampled air. The finding of organisms in the exhaled air was quite variable from patient to patient and did not correlate with sputum smear results.

Simple maneuvers, such as covering the mouth while coughing, can reduce formation of droplet nuclei by deflecting droplets from the air stream. Similarly, a mask worn by the patient is effective because particles are trapped while they are still large, before the water content has evaporated. Masks (disposable particulate respirators) worn by persons exposed to an infectious source are less effective than are masks worn by patients, because most airborne droplet nuclei are much smaller than their parent droplets. However, properly constructed, well-fitting masks are very efficient in removing respirable particles of 1 to 5 μm ³⁸ (see also Chapter 11).

A second factor of the source case to be considered in determining infectiousness is the number of organisms contained in the lungs. This can be inferred from the extent and morphology of the disease, as determined by the chest radiograph and more directly estimated by microscopic examination of sputum. Canetti demonstrated that the bacillary population of tuberculous lesions varies greatly, depending on the morphology of the lesion.³⁹ The number of bacilli in solid nodular lesions ranges from 10^2 to 10^4 organisms, whereas in cavitory lesions, populations are on the order of 10^7 to 10^9 bacilli. Loudon and Spohn,⁴⁰ among others, demonstrated that the prevalence of tuberculin reactors among young contacts of patients with newly discovered tuberculosis increased as the radiographic extent of involvement increased. Thus, in tuberculosis control, the contacts of persons with more extensive tuberculosis should be accorded a higher priority for evaluation than the contacts of persons with less severe disease.

The most direct means of estimating bacillary population is microscopic examination of properly stained sputum smears. An average viable bacillary population of 5000 to 10,000 organisms per milliliter of sputum is required for the organisms to be seen in an acid-fast-stained sputum smear.⁴¹ The contacts of patients who have organisms present in sputum smears have a much higher prevalence of infection than do contacts of patients with negative smears and either positive or negative cultures.⁴² However, the contacts of sputum smear-negative patients may still acquire tuberculous infection and develop tuberculosis. Transmission from smear-negative patients was estimated to be the cause of approximately 17% of newly diagnosed cases in San Francisco.⁴³

A third important factor in determining the infectiousness of a source case is the use of chemotherapy. In studies designed to identify and quantify factors influencing transmissibility of *M. tuberculosis*, Sultan and associates⁴⁴ and Riley and coworkers³⁴ noted that patients who had positive sputum smears but who were receiving antituberculosis drugs were much less infectious for guinea pigs than were untreated patients. By their calculations, the relative infectiousness of untreated patients in comparison with treated patients was 50:1. Escombe and coworkers,³⁵ as already noted, came to a similar conclusion. Consistent with these

experimental observations, a substantial body of clinical data has accumulated that indicates that, once treatment to which the organisms are susceptible is begun, transmission of *M. tuberculosis* decreases quickly. The quantification of the infectiousness of cough-generated aerosols has shown the same result—that the major factor associated with persistent culture-positive aerosols was lack of effective treatment during the previous week.³⁷ The most important mechanism by which chemotherapy reduces infectiousness is the direct effect of the drug on the bacillary population in the lungs. Hobby and associates⁴¹ found that, after an average of 15.6 days of multidrug chemotherapy, there was a reduction in the number of tubercle bacilli per milliliter of sputum of at least 2 logs, from approximately 10^6 to approximately 10^4 , or a 99% decrease. These data are similar to those reported by Jindani and coworkers, who demonstrated a reduction in colony counts of nearly 2 logs per milliliter of sputum in the first 2 days of treatment and a further reduction of 1 log during the next 12 days.⁴⁵ Thus, in the initial 2 weeks of treatment, there was a decrease from approximately 10^7 to 10^4 organisms per milliliter of sputum, or a reduction of 99.9%. However, even with this profound reduction in the bacillary population, the remaining number of organisms (10,000 per milliliter of sputum) would still be sufficient to produce a positive acid-fast sputum smear. In addition to reducing the number of viable bacilli, chemotherapy also promptly decreases coughing. Loudon and Spohn⁴⁰ noted that coughing was reduced by 40% after 1 week of treatment and by 65% after 2 weeks. The sum of these effects is that, once a patient with tuberculosis is placed on effective therapy, transmission of tubercle bacilli ceases to be a concern. The decline in infectiousness is caused mainly by the rapid reduction in bacillary population in the lungs as a result of antituberculosis chemotherapy, particularly isoniazid. Drug regimens that do not include isoniazid probably should not be expected to render the patient noninfectious as rapidly as do those containing isoniazid. Likewise, the prompt reduction in infectiousness cannot be assumed in patients harboring organisms that are resistant to isoniazid.

Different strains have different infectiousness. For example, strains of *M. tuberculosis* resistant to isoniazid may be less pathogenic than fully susceptible organisms.^{46,47} Molecular epidemiologic studies suggest that the mutation conferring resistance may have a role in the pathogenicity of *M. tuberculosis*, especially mutations associated with isoniazid resistance.⁴⁸ Isolates harboring the most common mutation, *katG* S315T and the *inhA* promoter 15c-t, were able to cause secondary cases of tuberculosis (defined as genotypic clustering of strains in a population). In contrast, mutations in *katG* other than the common S315T mutation did not cause secondary cases. Although more information is necessary to confirm this association, this finding may explain the different results regarding the pathogenicity of some drug-resistant strains. It is also clear that the lesser pathogenicity can easily be offset by a prolonged period of infectiousness, as might be expected with ineffective treatment, as suggested by Escombe and associates,³⁵ or with exposure of an immunocompromised host. Outbreaks of tuberculosis caused by MDR and XDR strains of tubercle bacilli have taken place in hospitals or correctional facilities and disproportionately involve HIV-infected

persons,⁴⁹ although immunocompetent persons have also been involved.

The operational implications of these assumptions concerning infectiousness should be modified in accordance with the patient's living and working circumstances. The general principles of infection control entail an assessment of the vulnerability to tuberculous infection of persons who will potentially be exposed and the consequences should those who are exposed become infected.

ENVIRONMENTAL FACTORS

The physical laws that apply to aerosolized particles, described in detail in Chapter 11 dictate that droplet nuclei essentially become part of the environmental air; thus, environmental factors are of extreme importance in influencing transmission of tubercle bacilli. Studies by Loudon and associates⁵⁰ showed that, under standard conditions of temperature and humidity indoors, 60% to 71% of aerosolized *M. tuberculosis* organisms survived for 3 hours, 48% to 56% for 6 hours, and 28% to 32% for 9 hours. Apart from the natural death rate, the only factors influencing the infectiousness of organisms in a droplet nucleus under ordinary circumstances are its removal by venting or filtering and the death of the organisms from exposure to ultraviolet light. Environmental factors may be manipulated to decrease the concentration of tubercle bacilli, mainly removing them by effective filtration, killing them with ultraviolet light, or both.⁵¹ The influence of the concentration of organisms in environmental air in transmission of *M. tuberculosis* has been well illustrated in several microepidemics in which recirculation of air played an important role. The most dramatic example happened on board a U.S. Navy vessel that had a closed, recirculating ventilation system.⁵² The index case had a positive sputum smear and a brisk cough. As a result of this one case, 53 of 60 persons (88%) in his berth compartment acquired tuberculous infections and 6 developed tuberculosis. In a second compartment connected to the same ventilation system, 43 of 81 persons (53%) became infected and 1 developed tuberculosis. Smaller epidemics, one caused by a patient who underwent bronchoscopy in an intensive care unit, have been described.⁵³

Since early in the 20th century, it has been known that exposure to ultraviolet radiation kills tubercle bacilli. Riley and coworkers,³⁴ in their classic studies of infectiousness in a series of patients, demonstrated that ultraviolet irradiation of air passing through an air-conditioning duct completely eliminated transmission of *M. tuberculosis* to guinea pigs housed beyond the ultraviolet lights. The major usefulness of ultraviolet lights is for providing UV irradiation of room air, using appropriately shielded lamps on the upper walls in hospital areas or clinics where patients with untreated tuberculosis are likely to be encountered. This is especially important in open areas such as waiting rooms, where ventilation may not be adequate to remove infectious particles, and within ventilation systems.⁵¹

CIRCUMSTANCES OF EXPOSURE

The conditions of exposure have a major influence on the number of infectious particles inhaled. If the exposure is of long duration and takes place under conditions that would

be associated with a high concentration of droplet nuclei in the air inhaled by the contact, there is obviously a greater likelihood of transmission. This is simply a restatement of what has been known for many years: Crowding and intimacy of contact are important determinants of transmission of *M. tuberculosis*.⁵⁴ This is reflected in data from the United States showing that rates of both clinical tuberculosis and tuberculin reactivity are much higher among close (generally household) than among nonclose (generally out-of-household) contacts. In general, the rate of tuberculosis is in the range of 15 per 1000 close contacts and 3 per 1000 nonclose contacts. Of close contacts, approximately 50% are infected, in comparison with approximately 15% of nonclose contacts.⁵⁵ Because the risk of tuberculosis is higher among close contacts, they should also be considered high-priority candidates for isoniazid preventive therapy. However, a number of studies using molecular epidemiology to track transmission dynamics have shown that substantial transmission may take place outside the household, particularly in social gathering places such as bars or informal places where alcohol is consumed.⁵⁶

HOST FACTORS

There is substantial evidence that susceptibility to acquisition of infection with *M. tuberculosis* is highly variable. Most descriptions of contact investigations report that 40% to 60% of close contacts of an index case become infected, as reflected by conversion of the *tuberculin skin test* (TST) or *interferon* (IFN)- γ *release assay* from negative to positive. Although variations in the intensity of exposure contribute to the likelihood of becoming infected, variations in host susceptibility are also likely to contribute. Strong evidence for variable susceptibility to acquisition of infection with *M. tuberculosis* was provided by a prospective study of student nurses in a tuberculosis hospital in Philadelphia in the prechemotherapy era.⁵⁷ In that study, in which student nurses were assigned to rotations on the same tuberculosis wards, 30% remained uninfected (TST unreactive) after 2 years of nursing school, indicating that despite repeated exposure, some of the student nurses were less susceptible to acquisition of infection than others. However, by the end of the third year of nursing school, 100% of the students had become infected, indicating that resistance to infection is

quantitative, not absolute, and can be overcome by sufficient exposure to especially virulent strains of bacteria.

There have been few efforts to identify the determinants of resistance to acquisition of infection, although a recent study in a high-prevalence community in South Africa presented evidence for at least one host genetic determinant that influences the likelihood of acquisition of infection in children. Genomewide linkage analysis of TST-unreactive (zero-mm induration) and TST-reactive (greater than zero; median, 11.2-mm induration) children revealed evidence of a major locus that maps to chromosome region 11p14.⁵⁸ The identity of the gene(s) at that locus, together with analysis of the cellular distribution and regulation of expression and the functions of the gene products, may reveal important mechanistic information on human resistance to acquisition of infection with *M. tuberculosis*.

It is currently unclear whether HIV infection, which has a major effect on progression to active tuberculosis, also affects susceptibility to acquisition of infection.⁵⁹

PATHOGENESIS

The genesis of the pathologic reactions in tuberculosis is inextricably linked with the response of the host to the invading tubercle bacillus. In most individuals infected with *M. tuberculosis*, the host response—innate and adaptive—restricts the growth of the pathogen, thereby containing the infection.⁶⁰ Paradoxically, however, the immunologic response to *M. tuberculosis* is likely responsible for the characteristic presentation of tuberculosis.⁶¹ In contrast, the near absence of cell-mediated adaptive immunity in patients with advanced HIV infection is assumed to be responsible for the atypical presentations of tuberculosis in HIV-infected patients. Such patients tend to have multisystem involvement and tend not to have cavitary lung lesions.⁶² Although the lack of immune response minimizes tissue damage, the organism is not met with an effective protective response, thus facilitating proliferation and dissemination of the bacilli.

Figure 35-3 describes schematically the events and outcomes that result from human exposure to *M. tuberculosis*. There are two phases: the acquisition of infection and the subsequent development of tuberculosis. Tuberculosis may

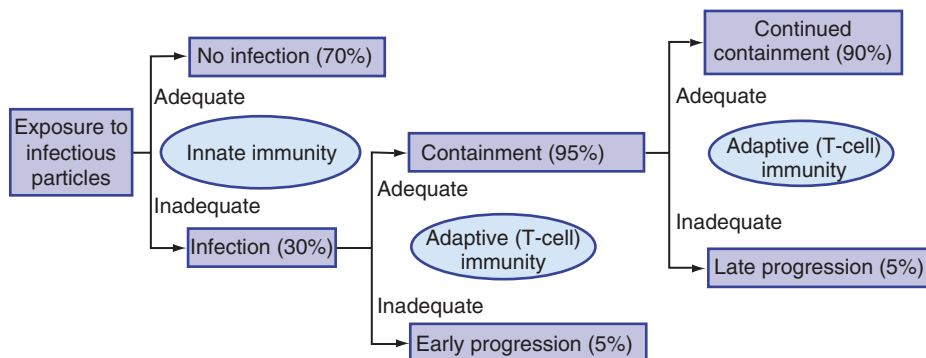

Figure 35-3 Consequences of exposure to an infectious source of tuberculosis depending on the status of immunity. Exposure to a patient with infectious tuberculosis causes tuberculous infection in approximately 30% of those exposed. Of those who are infected, 3% to 10% develop tuberculosis within 1 year of their becoming infected. Beyond 1 year, an additional 3% to 5% develop tuberculosis during the remainder of their lifetimes.

develop as direct progression from infection to disease (3% to 10% probability within 1 year of infection) or from late progression many years after infection (up to 5% probability for the lifetime of an infected person after the first year of infection).⁶³ In HIV-infected populations, the rate of developing disease is considerably higher.⁶²

Although *M. tuberculosis* possesses many features in common with other bacteria, unique characteristics that are restricted to *M. tuberculosis* and its close phylogenetic relatives are responsible for the distinct pathogenesis of tuberculosis. These unique features, principally consisting of specific secreted proteins and biologically active complex lipids, have been characterized by a combination of in vitro studies, studies in experimental animals, and studies in humans. Together, these unique features account for much of the cellular, subcellular, and molecular pathogenesis of tuberculosis.

INTRACELLULAR TRAFFICKING OF MYCOBACTERIUM TUBERCULOSIS

Seminal studies by Armstrong and D'Arcy-Hart and colleagues^{64,65} revealed that pathogenic mycobacteria survive and replicate in host phagocytes, including macrophages, by perturbing the normal pathway of phagosome maturation that eventuates in fusion with lysosomes and killing and digestion of other pathogens. Subsequent studies in basic cell biology have revealed that phagolysosome formation follows an ordered series of interactions between phagosome membrane proteins and phospholipids, relying on proteins that regulate intracellular traffic. One of these regulatory proteins, a low-molecular-weight GTPase termed Rab7, is essential for the late step of phagosome acquisition of lysosomal constituents; *M. tuberculosis* disrupts recruitment of Rab7 to the phagosome membrane.⁶⁶ Normal trafficking also requires conversion of phagosome membrane phosphatidylinositol to phosphatidylinositol-3-phosphate; virulent mycobacteria also interfere with this essential step by mechanisms that remain incompletely defined. Together, these mechanisms allow *M. tuberculosis* to survive and replicate intracellularly. Recent studies have revealed an additional requirement for the ESCRT (Endosomal Sorting Complex Required for Transport) pathway of intracellular vesicle trafficking in phagosome maturation,⁶⁷ and there is strong evidence that EsxH, a protein secreted by *M. tuberculosis*, disrupts the ESCRT pathway.⁶⁸ In addition, the autophagy system, originally characterized for its role in degradation of endogenous cellular proteins and organelles, has received considerable attention for its role in restricting growth of intracellular mycobacteria,⁶⁹ especially after stimulation of cells by the cytokine, IFN- γ . However, *M. tuberculosis* employs mechanisms to evade autophagy, including disruption of the phagosome membrane, giving the bacteria access to the host cell cytoplasm.⁷⁰⁻⁷² Thus, *M. tuberculosis* can occupy several distinct intracellular niches: immature phagosomes, autophagosomes, and the cytoplasm.

ESX-1 PROTEIN SECRETION SYSTEM

The *early secreted antigen 6 kilodaltons (ESAT-6) secretion system 1 (ESX-1)* was the first bacterial type VII secretion

system to be discovered and is essential for virulence of *M. tuberculosis*. This was first indicated by the discovery that all strains of BCG, the attenuated strain of *M. bovis* used as a vaccine for tuberculosis, lack a functional ESX-1 system.⁷³⁻⁷⁵ Of the proteins secreted by the *M. tuberculosis* ESX-1 system, ESAT-6 and *culture filtrate protein of 10 kD (CFP-10)* are the best characterized. These proteins are not present in BCG and, thus, confer specificity to IFN- γ release assays in the diagnosis of latent tuberculous infection.

Although multiple properties have been attributed to ESX-1-secreted proteins, the best characterized are their effects on host membrane integrity. ESX-1-deficient bacteria do not escape the phagosome⁷² and do not stimulate host signaling pathways whose sensing mechanisms are in the cytoplasm,⁷⁰ indicating that one target of the ESX-1 proteins is the phagosome membrane. ESX-1-deficient mycobacteria are also defective in cell-to-cell spread, most likely because they are less able to cause host cell necrosis; with cell necrosis, bacteria are released to the extracellular space, where they can access adjacent cells that support subsequent rounds of bacterial replication.^{73,74,76,77} Studies of the purified protein have directly implicated ESAT-6 in membrane perturbation. ESAT-6 has also been implicated in stimulating epithelial cells to express matrix metalloproteinase-9, which promotes migration of uninfected macrophages to the region adjacent to dying infected macrophages when they release viable bacteria, thus sustaining the infection cycle.⁷⁸

M. tuberculosis possesses five type VII secretion systems, of which ESX-1 is the best characterized. Of the remainder, ESX-3 is essential for survival of *M. tuberculosis*⁷⁹ and contributes to pathogenesis; it is responsible for secretion of the protein, EsxH (also known as Tb10.4), which interferes with the host ESCRT pathway⁶⁸ and is also a frequent target for recognition by T cells of people infected with *M. tuberculosis*.

INDUCTION OF TYPE I INTERFERONS

An important aspect of tuberculosis pathogenesis is the induction of type I IFN (IFN- α and/or IFN- β) secretion. Whole blood transcriptome analysis to discover human genes that are differentially expressed in tuberculosis revealed a transcriptional signature dominated by IFN-responsive genes,⁸⁰ and this finding has been replicated in additional patient cohorts.⁸¹⁻⁸³ The strength of the IFN transcriptional signature correlates with the extent of disease, and the transcriptional signature is rapidly reversed with effective chemotherapy.⁸⁴ Whether type I IFN plays a pathogenic role or is a secondary effect of active tuberculosis in humans remains to be defined. However, in mice, there is evidence that type I IFNs play a pathogenic role in *M. tuberculosis* infection,⁸⁵ at least partially by enhancing recruitment of mononuclear cells that support intracellular bacterial replication.^{86,87} In addition, type I IFNs limit expression of *interleukin (IL)-1- β* , a cytokine that is essential for control of *M. tuberculosis*.^{88,89} A link between virulence and induction of a host-detrimental type I IFN response has been established by the observation that intact ESX-1 secretion and phagosome permeabilization are required for *M. tuberculosis* induction of type I IFN expression.^{70,71} Despite the growing evidence for a detrimental role

of type I IFNs in tuberculosis, therapeutic administration of type I IFN for multiple sclerosis or hepatitis C has not been accompanied by a striking increase in the frequency of active tuberculosis.

BIOLOGICALLY ACTIVE MYCOBACTERIAL LIPIDS

M. tuberculosis has long been known to be rich in lipids, including mycolic acids that possess acyl chains containing up to 90 carbons. However, rather than being a mere “waxy coat” that acts as a barrier to drugs and other polar molecules, mycobacterial lipids interact directly with the host to contribute to pathogenesis.

Trehalose dimycolate (TDM), an abundant cell wall lipid traditionally known as mycobacterial “cord factor,” modulates innate immune and inflammatory responses to *M. tuberculosis* and is sufficient to induce transient granuloma formation when injected into experimental animals. Deficiency of TDM decreases pathogenicity of a mutant strain of *M. tuberculosis* experimental animals,⁹⁰ indicating that the responses induced by TDM favor the bacteria. TDM is recognized by two related C-type lectin receptors, termed Mincle (also termed Clec4e)⁹¹ and MCL (also termed Clec4d),⁹² expressed on macrophages and dendritic cells, which transduce signals that result in proinflammatory cytokine production.

Other complex mycobacterial lipids contribute to pathogenesis by mechanisms that remain under investigation. *Phthiocerol dimycocerosate* (PDIM) is present in all clinical isolates examined, despite its frequent loss during serial passage of *M. tuberculosis* in liquid culture; the persistence of PDIM in clinical isolates implies that it is essential for pathogenesis but dispensable in culture.⁹³ PDIM-deficient mutants are less pathogenic than PDIM-replete bacteria in mice^{94,95}; PDIM masks the molecules recognized by Toll-like receptors and dampens initial inflammatory responses.⁹⁶ The structurally related lipoglycans, *phosphatidylinositol mannans* (PIMs) and *lipoarabinomannan* (LAM), are implicated in specific interactions with the host. PIMs can stimulate innate immune and inflammatory responses by serving as agonists for *Toll-like receptor-2* (TLR2),⁹⁷ and studies with LAM-coated beads have indicated a potential role for LAM in altering phagosome maturation.⁹⁸

GRANULOMAS

Granulomas, consisting of aggregates of macrophages, often including multinucleated giant cells and “epithelioid” macrophages together with variable numbers of lymphocytes, are a pathologic hallmark of tuberculosis. Granulomas can also contain variable numbers of necrotic cells and microscopic and macroscopic necrotic centers; some also exhibit *caseating* necrosis (characterized by complete loss of tissue structure and a texture resembling soft cheese) and may become calcified. Granulomas have been traditionally considered to be host-protective structures, thought to “wall off” bacteria and keep them from disseminating. Whereas this view may apply in later stages of fibrotic and calcified granulomas, early granuloma formation actually promotes infection by facilitating cell-to-cell spread within the macrophage aggregates, thus optimizing expansion of

the bacterial population.⁷⁶ In addition, intravital microscopy has revealed that macrophages and lymphocytes in granulomas are dynamic, with lymphocytes freely migrating between the apparently closely apposed macrophages.⁹⁹ Together, these studies and others indicate that granulomas are dynamic structures that may benefit either the pathogen or the host, depending on the stage of infection.

MODULATION OF APOPTOSIS

As a facultative intracellular pathogen, *M. tuberculosis* shapes its environment to optimize its survival and growth. One mechanism is to inhibit apoptosis (programmed cell death) and prolong the life of infected cells, allowing the bacteria to grow to a larger population size in each infected cell before spreading to adjacent cells.¹⁰⁰ There are other benefits to *M. tuberculosis* from inhibiting apoptosis. Because uptake of apoptotic cell fragments by naive macrophages results in killing of the bacteria formerly residing in an apoptotic cell, inhibition of apoptosis allows *M. tuberculosis* to evade this mode of death.¹⁰¹ Because bacterial antigens associated with apoptotic cell fragments are subject to uptake and “cross-presentation” to CD8 T cells, inhibition of apoptosis of the infected cells minimizes the frequency of CD8 T-cell activation.¹⁰² Evidence that inhibition of apoptosis is a virulence mechanism in animal models of tuberculosis is provided by the findings that proapoptotic mutants of *M. tuberculosis* are less pathogenic in vivo.¹⁰³

PHYLOGENETIC LINEAGE- AND STRAIN-DEPENDENT VARIATION IN PATHOGENESIS

As noted earlier, use of high-resolution genotyping methods has recently revealed genetic diversity in the *M. tuberculosis* complex. This has provided a basis for comparative studies to understand the phenotypic consequences of genetic diversity. For example, *M. africanum*, which represents a distinct genetic lineage of the *M. tuberculosis* complex and is endemic in West Africa, compared with strains of other lineages, is less pathogenic at specific steps in the infection cycle. It is transmitted as readily as members of other lineages, but the progression to disease is less frequent than other lineages.²⁰ Yet once active tuberculosis develops with *M. africanum*, it is clinically indistinguishable from tuberculosis due to other lineages. Evidence that these findings are not strictly attributable to host population differences is provided by finding that *M. africanum* is also less pathogenic in inbred mice.¹⁰⁴ As another example, a subfamily of the Beijing family has been found to be more readily transmitted than other strains in the same community and causes more severe disease in experimentally infected guinea pigs.^{22,23} These examples provide evidence for intrinsic differences in strains of *M. tuberculosis* and indicate that studies linking epidemiology and pathogenesis (using animal models) can provide complementary information.

LATENCY/DORMANCY AND REACTIVATION

One of the most important characteristics of tuberculosis is the state of latent infection, which develops in the

majority of infected humans, with the ability to reactivate and cause active, transmissible disease. Although host factors (described later) contribute to establishing and maintaining the latent state, the bacteria also possess highly evolved mechanisms that are involved in latency and reactivation. A considerable amount of recent work has focused on certain *M. tuberculosis* genes in which expression is induced by hypoxia, and which are believed to be involved in latency (modeled as bacterial dormancy, wherein most of the bacterial population is not actively dividing). One group of genes whose expression is controlled by the transcription factor, *dosR*, is induced transiently by hypoxia, while other genes, collectively termed the *Enduring Hypoxic Response*, are under alternative regulation.^{105,106} Together with evidence that reoxygenation reverses the changes in gene expression, these findings provide a paradigm for understanding how *M. tuberculosis* can reversibly adapt to its environment and alter its metabolic and growth state. Evidence that such mechanisms operate during latent tuberculosis infection in humans is provided by the finding that T-cell responses to proteins encoded by these “dormancy” genes are more common in individuals with latent infection than in those with active tuberculosis.^{107,108}

The contributions of bacterial determinants to reactivation of latent infection are less well understood than are those associated with latency. However, the *M. tuberculosis* genome encodes 5 proteins with homology to a family of “resuscitation promoting factors” (RPFs) characterized in other bacteria for their ability to stimulate growth of bacteria from stagnant cultures. Although RPFs in other bacteria may act in interbacterial communication, the *M. tuberculosis* RPFs characterized to date are peptidoglycan glycosidases and appear to be involved in remodeling of the cell wall. Mutant strains of *M. tuberculosis* in which the genes encoding RPFs have been deleted are defective for reactivation in animal models,^{109–111} suggesting that RPFs may contribute to progression from latent to active tuberculosis in humans.

IMMUNITY

Countering the highly evolved pathogenetic mechanisms of *M. tuberculosis* are the host responses that limit progression from infection to disease. Although the mechanisms that determine whether an exposed individual will become infected or not (see Fig. 35-3) have not yet been identified, the mechanisms that determine the outcome after infection are increasingly well understood.

INNATE IMMUNITY TO MYCOBACTERIUM TUBERCULOSIS

Innate immunity includes cellular and humoral defenses that do not depend on clonal rearrangement of antigen receptor genes, the defining feature of acquired immunity as carried out by B and T lymphocytes. Although innate immune responses play an important role in tuberculosis, evidence from studies in individuals with HIV and in animal models have established that innate immunity is insufficient for control of *M. tuberculosis* infection.

Innate Immune Cells in Tuberculosis

M. tuberculosis interacts with diverse cell types. Macrophages have been the longstanding target of attention, ever since the studies of Florence Sabin and colleagues^{112,113} in the 1920s revealed that tubercle bacilli dwell in mononuclear cells. Although alveolar macrophages are widely believed to be the initial cells to encounter *M. tuberculosis* after inhalation of small droplet nuclei, the inflammatory macrophages recruited to the site of infection from the blood are likely to be the major reservoirs of the bacteria. In addition, neutrophils^{114–116} are increasingly recognized as having important roles as cellular sites of infection and contributors to innate immune responses in tuberculosis. In close contacts of pulmonary tuberculosis cases, a lower neutrophil count was associated with a higher likelihood of acquiring infection, and neutrophils contributed to killing of *M. tuberculosis* in an in vitro whole blood assay.¹¹⁶ Dendritic cells have also been shown to contain *M. tuberculosis* both in humans and experimentally infected mice^{117,118}; these cells serve as the dominant source of the cytokine IL-12, and they transport tubercle bacilli from the lungs to the local draining lymph nodes, where antigen-specific T-cell responses are initiated.¹¹⁹ Mononuclear phagocytes, especially dendritic cells and cytokine-activated macrophages, are also specialized to present mycobacterial antigens for recognition by CD4⁺ T cells.

M. tuberculosis enters macrophages, dendritic cells, and neutrophils by undergoing phagocytosis, using any of multiple distinct receptors that recognize ligands expressed on the bacteria.¹²⁰ In addition to phagocytic receptors, specific components of the bacteria are recognized by pattern-recognition receptors including TLR 2, 4, and 9; NOD2; DC-SIGN; Dectin-1; Mincle; and MCL.¹²¹ These receptors do not mediate phagocytosis but initiate signaling that results in secretion of specific proinflammatory and anti-inflammatory cytokines, as well as cell activation and differentiation.

In addition to mononuclear and polymorphonuclear phagocytes, certain innate lymphocytes, including *natural killer T* (NKT) cells and at least two subsets of innate T lymphocytes, respond to *M. tuberculosis* infection¹²² and are believed to be a source of cytokines early after infection, before adaptive immune responses are activated. NKT cells recognize host molecules expressed on stressed cells while invariant NKT cells recognize complex host and foreign lipids bound to the HLA class I-related molecule, CD1d. In vitro studies indicate that invariant NKT cells can be activated to secrete IFN- γ and granulysin and restrict growth of intracellular *M. tuberculosis*.¹²³ Invariant NKT cells are depleted from the blood in patients with active tuberculosis, indicating that they are involved in the response to *M. tuberculosis* in vivo.^{124,125} *Mucosal-Associated Invariant T cells* (MAITs) recognize bacterial metabolites of B vitamins, bound to an HLA class I-like molecule termed MR1, and are activated by cells infected with *M. tuberculosis* or certain other bacteria.^{126,127} Their abundance and location suggest that MAITs may be involved in clearance of *M. tuberculosis* inhaled in droplet nuclei that are too large to reach the alveoli. MAITs are depleted from blood in people infected with HIV, most likely

through an indirect effect, and are not fully reconstituted with antiretroviral therapy.^{128,129}

Molecular Mediators of Innate Immunity in Tuberculosis

Macrophages and dendritic cells respond to *M. tuberculosis* by secreting cytokines with distinct activities that contribute to control of infection and regulate specific aspects of immunity. Of the cytokines induced by *M. tuberculosis*, tumor necrosis factor (TNF) is especially well characterized as essential for immunity to tuberculosis in humans. Patients with rheumatoid arthritis and other conditions that are treated with agents that block TNF activity have up to a 25-fold higher risk of tuberculosis than in control populations¹³⁰ and are more likely to have disseminated infection.¹³¹ The risk of tuberculosis is higher in patients treated with neutralizing antibodies to TNF than with soluble receptor analogues.¹³⁰ TNF contributes to immunity to tuberculosis by activating microbicidal activities of macrophages¹³² and by modulating death of infected cells.¹³²⁻¹³⁴ In addition, one of the antibodies to TNF, infliximab, when administered to patients with rheumatoid arthritis, depletes a specific subset of CD8⁺ T cells that contain membrane-bound TNF and contribute to killing intracellular *M. tuberculosis* in an in vitro assay.¹³⁵

IFN- γ plays an essential role in immune control of tuberculosis. IFN- γ -deficient^{136,137} or IFN- γ receptor-deficient⁸⁷ mice succumb to rapidly progressive *M. tuberculosis* infection and, in patients with IFN- γ receptor mutations, tuberculosis is especially clinically severe (disseminated and/or recurrent).¹³⁸ IFN- γ is believed to contribute to immune control of tuberculosis through activating the microbicidal activities of macrophages, including through autophagy,^{139,140} and by modulating inflammation at the site of infection.^{87,141} Although multiple cell types can be sources of IFN- γ , the principal cellular sources are lymphocytes, including innate T cells, as well as adaptive CD4⁺ and CD8⁺ T cells.

Interleukin-12 (IL-12) is another essential innate cytokine for immunity to tuberculosis. The best-characterized role of IL-12 is in directing differentiation of CD4 T cells into type 1 T helper (Th1) cells that secrete IFN- γ and contribute to control of tuberculosis (see later). Evidence that IL-12 is essential for control of tuberculosis is provided by experiments in IL-12-deficient mice^{142,143} and by observations that children with mutations in the IL-12 receptor beta-1 chain are susceptible to tuberculosis and other mycobacterial infections.¹⁴⁴

Finally, vitamin D has been shown by increasingly strong evidence to contribute to human immunity to tuberculosis. Vitamin D and tuberculosis share a long history; indeed, some believe that if there was a benefit of sanatoria, it may be attributable in part to “heliotherapy,” exposure to sunlight, causing activation of vitamin D. More pertinent is that multiple studies have found low serum vitamin D levels in patients with tuberculosis (reviewed in Martineau¹⁴⁵). Moreover, a prospective study found that household contacts of persons with infectious tuberculosis were more likely to progress to active disease if they were vitamin D deficient at baseline.¹⁴⁶ In vitro studies have demonstrated that vitamin D treatment of *M. tuberculosis*-infected human macrophages leads to restriction of intracellular bacterial

replication through induction of the antibacterial peptide, cathelicidin.^{147,148} Additional studies have revealed that vitamin D is essential for the antimycobacterial action of IFN- γ on human macrophages, acting through induction of cathelicidin and activation of autophagy.¹³⁹ So far, attempts to augment the effects of chemotherapy for tuberculosis by the addition of vitamin D have had limited effects on microbiological end points¹⁴⁵ but clearly accelerate the resolution of inflammation.¹⁴⁹

ADAPTIVE IMMUNITY TO MYCOBACTERIUM TUBERCULOSIS

Early studies of the mechanisms of immunity to mycobacteria found that adoptive transfer of cells, but not serum, conferred cutaneous hypersensitivity to tuberculin on the recipients.¹⁵⁰ This initial observation was followed by studies that revealed that cell transfer also improved the ability to control mycobacteria¹⁵¹⁻¹⁵³ and that the responsible cells were T lymphocytes.¹⁵⁴ Thus, the focus of immunology studies in tuberculosis has been on T cells rather than antibodies.

CD4⁺ T Cells

CD4⁺ T cells are essential for immunity to tuberculosis. In mice, depleting CD4⁺ cells or impairing their development (by deleting MHC class II molecules, which bind antigenic peptides and are essential for development of CD4⁺ T cells) markedly accelerates the lethal course of infection.¹⁵⁵ In humans coinfecting with HIV, the progressive depletion of CD4⁺ cells increases the risk of tuberculosis and reconstitution of CD4⁺ T cells by antiretroviral therapy reduces the risk of tuberculosis.⁶² In addition to increased risk of tuberculosis per se, profound depletion of CD4⁺ T cells by HIV alters the clinical manifestations, with a higher frequency of extrapulmonary disease and a lower frequency of cavitary lung lesions.⁶²

Although the principal function of CD4⁺ T cells is to secrete cytokines such as IFN- γ , TNF, IL-2, IL-4, IL-17, or IL-22, some CD4⁺ T cells also possess cytolytic activity and can kill *M. tuberculosis*-infected cells.¹⁵⁶ Several studies have revealed that multifunctional CD4⁺ T cells (which produce multiple distinct cytokines per cell) are more common in subjects with latent TB infection, while monofunctional CD4⁺ T cells (which produce only one cytokine, usually TNF) are more common in those with active tuberculosis.^{157,158} Together, these findings indicate that multifunctional T cells may be especially important in preventing progression from latent to active tuberculosis.

CD8⁺ T Cells

Patients also develop antigen-specific CD8⁺ T-cell responses in tuberculosis. Although the functional contribution of CD8⁺ T cells in human tuberculosis is not well defined, CD8⁺ T cells contribute to control of *M. tuberculosis* in experimentally infected cattle and mice.¹⁵⁹ Evidence for a functional role of human CD8⁺ T cells in tuberculosis is provided by the discovery that treatment of patients with rheumatoid arthritis with the anti-TNF antibody, infliximab, increases the risk of tuberculosis and depletes a specific subset of CD8⁺ T cells that contribute to killing of *M. tuberculosis* in vitro.¹³⁵ *M. tuberculosis* antigen-specific CD8⁺ T cells are

detected more frequently in active tuberculosis than during latent infection,¹⁶⁰ suggesting that CD8⁺ T cells principally respond when the bacterial burden is especially high.¹⁶¹

***Mycobacterium Tuberculosis* Antigens Recognized by Human T Cells**

Classical T cells recognize peptide fragments of proteins (including from bacteria), bound to MHC (HLA in humans) class II (CD4⁺ T cells) or class I (CD8⁺ T cells) molecules on dendritic cells and macrophages. Although most studies have focused on a restricted number of secreted *M. tuberculosis* antigens, emerging evidence indicates that a broad range of mycobacterial proteins can provide peptide fragments (epitopes) that bind HLA class II molecules and are recognized by CD4⁺ T cells of people infected with *M. tuberculosis*.¹⁶²

In addition to providing protection against active disease, T-cell responses to *M. tuberculosis* antigens are the basis for TST and for *IFN-γ* release assays (IGRA, such as Quantiferon-TB and T-SPOT.TB). As noted in a separate section, the enhanced specificity of IGRAs over TSTs for *M. tuberculosis* infection is due to the use of two antigens (ESAT-6 and CFP-10) that are present in all strains of *M. tuberculosis* and uniformly absent from BCG vaccines. Insight into another potential basis for discordant results between TSTs and IGRAs is provided by the identification of antigens present in the *purified protein derivative* (PPD) used for TSTs. PPD is dominated by the presence of *M. tuberculosis* chaperone proteins (termed GroES, GroEL2, HspX, and DnaK), and contains little ESAT-6 or CFP-10.¹⁶³ Therefore, these diagnostic tests, in addition to depending on different procedures, measure responses to different bacterial antigens.

CONTRIBUTIONS OF IMMUNE RESPONSES TO TUBERCULOSIS PATHOLOGY

Tuberculosis is a prime example of an infection in which immune responses clearly contribute to the pathology of the disease, suggesting that the balance between protection and pathology requires tight regulation. For example, treatment with immunosuppressive corticosteroids predisposes to tuberculosis,¹⁶⁴ can mask the symptoms and reduce the radiographic manifestations of pulmonary tuberculosis,¹⁶⁵ and prevents mortality in some patients with tuberculous meningitis.^{166,167}

Analogous to autoimmune diseases such as type 1 diabetes mellitus and multiple sclerosis, T-cell responses can contribute to tissue destruction in tuberculosis. In mice selectively lacking PD-1, a molecule that transmits inhibitory signals in T cells, *M. tuberculosis* infection is rapidly lethal, due to excessive CD4⁺ T-cell activation and very high levels of proinflammatory cytokines.¹⁶⁸ In humans coinfecting with HIV, the frequency of cavitory lesions on chest radiographs is directly correlated with the CD4⁺ T-cell count at the time of diagnosis of tuberculosis.⁶² Since cavitory tuberculosis causes more secondary cases than noncavitory tuberculosis,^{169,170} mycobacterial induction of detrimental T-cell responses may benefit the bacteria by promoting transmission. Examination of the human T-cell epitopes in diverse strains of *M. tuberculosis* revealed a high level of sequence conservation (rather than variation, as in

the antigenic targets in other pathogens), implying an evolutionary benefit to the bacteria from T-cell recognition.¹⁴ These results suggest that T-cell responses to *M. tuberculosis*, which provide a benefit to infected people, can also benefit the bacteria by promoting pathology in a fraction of infected people, resulting in enhanced transmission. This finding may guide tuberculosis vaccine antigen selection and emphasizes the need to evaluate the potential adverse effects of new tuberculosis vaccines.

EXOGENOUS VERSUS ENDOGENOUS INFECTION

One of the historical controversies in tuberculosis has been the extent to which tuberculosis can be attributed to new infection by recently inhaled exogenous organisms (i.e., from the environment) as opposed to a reactivation of viable bacilli that have been maintained for many years in a dormant or growth-restricted state within the body.¹⁷¹ This concept is important in that current tuberculosis control efforts are based largely on the idea that most tuberculosis in low-incidence areas is the result of endogenous reactivation. Thus, prevention entails identification of infected persons and giving them preventive therapy with isoniazid.

Since the early 1990s, genotyping of *M. tuberculosis* has been successfully used to determine if tuberculosis is due to exogenous or endogenous infection. *M. tuberculosis* DNA fingerprinting derived from different genotyping markers and methods has been used to track specific isolates of *M. tuberculosis* in a community.¹⁷² For example, isolates of tubercle bacilli from HIV-positive individuals, in health care facilities or correctional institutions, frequently show identical genotypes (Fig. 35-4), indicating that these individuals

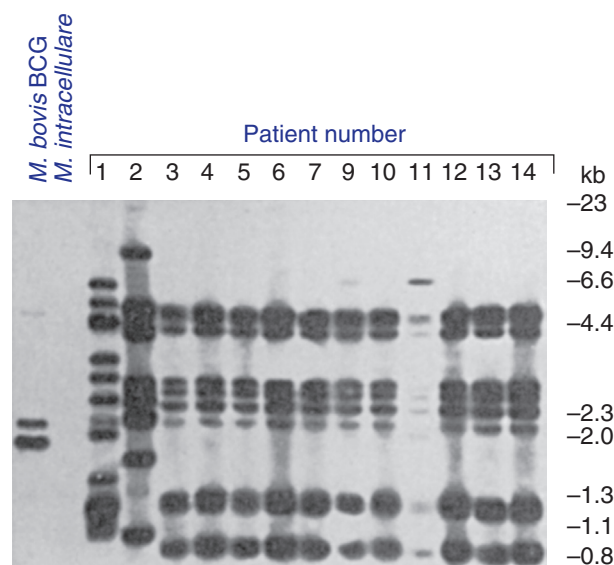

Figure 35-4 Gel electrophoresis of DNA extracted from organisms isolated from patients in an outbreak of tuberculosis in San Francisco. Cases 3 through 14 were linked epidemiologically, whereas cases 1 and 2 were not. This is an example of the use of restriction fragment length polymorphism analysis to track strains of *Mycobacterium tuberculosis*. (From Daley CL, Small PM, Schechter GF, et al: An outbreak of tuberculosis with accelerated progression among persons infected with the human immunodeficiency virus: an analysis using restriction fragment length polymorphisms. *N Engl J Med* 326:231–235, 1992.)

were probably infected by the same source within the facility.^{59,173} In such situations, tuberculosis can be assumed to be due to a recent exogenous infection with rapid progression to active tuberculosis. In contrast, patients with a unique DNA fingerprint are considered to have tuberculosis due to reactivation of latent infection acquired previously. Genotyping methods can similarly be used to differentiate relapse from reinfection in a patient with recurrent tuberculosis: a patient with relapse will have a similar *M. tuberculosis* DNA fingerprint in both episodes while a patient with reinfection will have different strains.¹⁷⁴⁻¹⁷⁷ Since the early 1990s, these markers have also enabled tuberculosis control programs, mainly in high-income settings, to track specific isolates of *M. tuberculosis* in a community¹⁷² to determine population-level risk factors for transmission, establish tailored public health strategies, and gauge the success of control measures.¹⁷⁸

The genetic markers used to track strains in the community are sufficiently polymorphic to distinguish among unrelated isolates yet stable enough to recognize isolates that are part of the chain of transmission. These markers include (1) the insertion element (IS) 6110,¹⁷⁹ (2) the *polymorphic GC-rich repetitive sequences* (PGRS), (3) polymorphisms in the *clustered regularly interspaced short palindromic repeats* (CRISPRs),¹⁸⁰ and (4) the *mycobacterial interspersed repetitive unit* (MIRU)–*variable number tandem repeats* (VNTRs).¹⁸¹ The genotypes using CRISPR (also known as spoligotypes) and MIRU-VNTR (MIRU-type) are currently widely used to track a strain in the community. For both methods, there are online databases in which researchers can compare (and submit) their genotypes.^{182,183} Most recently, the availability of high-throughput technology and the dramatic decrease in costs have allowed for the use of whole genome sequencing to identify mutations as markers to study transmission of *M. tuberculosis* in a community.¹⁸⁴⁻¹⁸⁹ Compared with the other genetic markers, whole genome sequencing allows the identification of microevolutionary events (i.e., single nucleotide polymorphisms) within a chain of transmission, identifies epidemiologic links, and determines the directionality of the transmission events.

RISK FACTORS FOR DISEASE

After acquiring an infection, not all persons are at equal risk of developing disease. Many conditions increase the likelihood of tuberculosis and serve as markers of increased risk. As noted previously, in healthy populations, the risk of developing tuberculosis is highest during the first year after infection; between 3% and 10% of newly infected persons develop tuberculosis during this period. The three factors presumably involved are the pathogenicity of the bacterial strain, the dose of bacilli implanted in the lungs, and the adequacy of the host response in countering the invasion. The “inoculum effect” (in which the likelihood of infection is directly related to the dose of bacteria) has not been clearly demonstrated in humans but is strongly suggested by results of animal experiments.³⁴ It is currently assumed that beyond the first year after infection has taken place, the immune response has fully developed, the number of organisms present has been substantially reduced, and the

remaining bacterial population has shifted to a state of persistence and slow replication. Understanding how this latent infection can shift to disease is critical in controlling tuberculosis.

Age is one risk factor. Among persons with tuberculous infection, case rates vary markedly with age. Rates are considerably increased in infants and relatively increased in adolescents and young adults.¹⁹⁰ The reasons for the variations are not fully understood but are likely to relate to age-dependent influences on the effectiveness of the immune response.¹⁹¹

HIV infection is by far the most potent risk factor worldwide. In the era before effective antiviral therapy, Selwyn and coworkers¹⁹² found that 8 of 212 HIV-infected intravenous drug users developed tuberculosis in a 2-year period of observation, a case rate of 8 per 100 person-years of observation. Of these, 7 cases developed within a subset of 49 persons who were known to be TST positive. Thus, the case rate for persons who were dually infected with both HIV and *M. tuberculosis* was 7.9 per 100 person-years, which exceeds the rate in a population with tuberculous infection without HIV infection. It also appears that the risk of rapid progression of tuberculosis among persons who are infected with HIV and who then become infected with *M. tuberculosis* is tremendously increased, as has been demonstrated in descriptions of two such outbreaks.^{59,193} The reported rates of tuberculosis in cohorts of persons with HIV infection vary widely and depend on the prevalence of tuberculosis in the environment, particularly the presence of infectious cases; the frequency with which treatment for latent tuberculous infection is used; the severity of immune compromise within the HIV-infected group; and whether dually infected persons are receiving antiretroviral therapy, which substantially reduces the risk.^{194,195}

The only study conducted to address the incidence of tuberculosis prospectively in a broad-based group of persons with HIV infection in the United States—before the widespread use of combined antiretroviral therapy—was the Pulmonary Complications of HIV Infection study.¹⁹⁶ In this cohort, drawn from six centers across the country, the rate of tuberculosis was 0.71 per 100 person-years of observation. In multivariate analyses, the factors that were associated with increased rates were residence in New York City or Newark (the two East Coast centers), being TST-positive (reaction > 5 mm), and having a CD4⁺ cell count below 200 cells/μL.

Antiretroviral treatment of HIV markedly reduces the incidence of tuberculosis, although the effect is not complete. A meta-analysis that included 11 published studies revealed that antiretroviral treatment and reconstitution of CD4⁺ T-cell counts reduces the incidence of tuberculosis as much as sixfold.¹⁹⁷ However, despite immune reconstitution to CD4 T-cell counts greater than 700 cells/μL, the incidence of tuberculosis in antiretroviral-treated HIV-infected people remains 4.4-fold higher than in HIV-uninfected people in the same community.¹⁹⁸

In persons with both HIV and tuberculous infections, antiretroviral therapy and preventive treatment with isoniazid substantially decrease the incidence of tuberculosis. In a retrospective analysis of the incidence of tuberculosis among persons with HIV infection in Rio de Janeiro, Brazil, among patients who received neither antiretroviral

treatment nor isoniazid preventive therapy, the incidence of tuberculosis was 4/100 person-years.¹⁹⁹ Among patients who received antiretroviral therapy, the incidence was 1.9/100 person-years (95% confidence interval [CI], 1.7 to 2.2), and those treated with isoniazid had a rate of 1.3/100 person-years (95% CI, 0.4 to 3.0). However, the incidence among patients who received both antiretroviral therapy and isoniazid was only 0.8/100 person-years (95% CI, 0.3 to 1.5). Thus, there was a 76% reduction in tuberculosis risk among patients receiving both antiretroviral treatment and isoniazid. (Isoniazid preventive therapy is discussed in a later section.)

Inhibition of TNF is the other well-characterized risk factor for tuberculosis. TNF can be antagonized by treatment with a biologic agent, either with a monoclonal antibody to TNF itself or soluble receptor analogues that block the interaction of TNF with its receptor. As mentioned, TNF contributes to immunity to tuberculosis by activating microbicidal activities of macrophages¹³² and by modulating apoptosis.^{132,133} Patients treated with TNF antagonists have up to a 25-fold higher risk of tuberculosis than in control populations.¹³⁰ Neutralizing antibodies to TNF increase the risk several fold more and induce tuberculosis sooner than the soluble receptor analogues.²⁰⁰ This may be in part because antibodies to TNF also deplete a subset of CD8⁺ memory T cells that contribute to killing intracellular *M. tuberculosis* in an in vitro assay.¹³⁵ Screening patients by TST, followed by treatment of latent tuberculosis infection before initiation of TNF antagonists, reduces the risk of active tuberculosis in these patient populations.²⁰¹

Other conditions or therapies that interfere with cell-mediated immunity also increase the risk of tuberculosis. These relationships, although well described and generally accepted, are poorly quantified. Examples of these disorders include hematologic malignancies and cancer chemotherapy. In addition, conditions such as diabetes mellitus²⁰² and uremia are thought to fit into this general category of risk-enhancing diseases, although the basis for this effect is not established. The risk of tuberculosis is also increased considerably in persons with silicosis,²⁰³ presumably owing to the effect of silica on the function of pulmonary macrophages.

Genetic risk factors have been suggested by twin studies in which there was a greater concordance of disease in monozygotic than in dizygotic twins.²⁰⁴ However, it is difficult to separate them from linked environmental factors. Case rates among persons infected with *M. tuberculosis* living in Denmark in the 1950s were only 28 per 100,000 per year.²⁰⁵ This contrasts strikingly with annual rates of 1500 to 1800 per 100,000 in Eskimo populations in Alaska and Greenland.²⁰⁶ Genetic differences are also suggested by the pattern of tuberculosis noted among Filipinos in the U.S. Navy, whose rate of disease increased with duration of enlistment, in contrast to the decrease observed in blacks and whites.²⁰⁷

Undernutrition is known to interfere with cell-mediated responses and thus is thought to account for the increased frequency of tuberculosis in malnourished persons.²⁰⁸ In addition to overt malnutrition, other factors related to specific but poorly defined nutritional deficiencies may also be associated with an increased risk of tuberculosis. For example, observations suggest that risk is increased in

persons who have had a gastrectomy or an intestinal bypass procedure for weight control.²⁰⁹ Body build has also been related to the risk of disease among infected persons. In U.S. Navy personnel, rates of tuberculosis were nearly three times greater among men who were thin for their height; the increased incidence of tuberculosis did not appear to be related to nutritional status in that group.²⁰⁷

Vitamin D deficiency has also been linked to tuberculosis. Studies on several continents have documented a higher frequency of vitamin D deficiency in patients with active tuberculosis than in control subjects. Moreover, a study in South Africa revealed reciprocal seasonal variations in serum vitamin D levels and tuberculosis notification rates: during the winter, vitamin D levels were lowest and tuberculosis notifications were greatest, whereas the converse was true in the summer.²¹⁰ Because in vitro studies have revealed a role for vitamin D in regulating macrophage expression of antimicrobial peptides that restrict intracellular growth of *M. tuberculosis*, it is likely that vitamin D deficiency increases the risk of tuberculosis, rather than for vitamin D deficiency to be a consequence of tuberculosis.

Despite the number of risk factors for tuberculosis that have been identified, the majority of cases have no identified immunological or physiological abnormality.

DIAGNOSIS OF LATENT TUBERCULOSIS INFECTION

As indicated previously, infection does not necessarily follow exposure to *M. tuberculosis*, but when infection develops, it causes a cell-mediated immune response that can be identified by a positive response to an intradermal test (TST) with purified protein derivative or a whole blood *IFN-γ* release assay (IGRA). Until recently the TST was the only test available to identify tuberculous infection. Although the TST continues to be used, IGRAs are widely used in high-resource settings.²¹¹⁻²¹³

TUBERCULIN SKIN TEST

Tuberculin was first prepared by Robert Koch in 1890 and was touted by him as being therapeutic for tuberculosis. Shortly thereafter, the diagnostic capabilities of the material were recognized through its use in animals. In 1934, Seibert and Glenn²¹⁴ prepared the first batch of a much more purified preparation, which they termed *purified protein derivative* (PPD). The most prevalent antigenic proteins in PPD are now known to be the bacterial heat shock proteins (or chaperonins) GroES, GroEL2, HspX, and DnaK.¹⁶³ The antigen is prepared in liquid form containing the detergent Tween 80 to decrease adsorption of protein to the glass of the vial. The standard intermediate tuberculin test consists of the intracutaneous injection (Mantoux method) of 0.1 mL of material, which contains 5 *tuberculin units* (TU). The site usually chosen is the volar surface of the forearm, but any accessible area can be used. A short-beveled 26- or 27-gauge needle should be used with a 1-mL graduated syringe. A properly placed intracutaneous injection should cause a well-demarcated wheal 6 to 10 mm in

diameter in which the hair follicles form dimples. Conventionally, the reading is done 48 to 72 hours after the injection, but it may be delayed for up to 1 week.²¹⁵

In persons such as hospital employees, who are likely to be tested repeatedly—if tuberculin negative at the outset—a two-step testing procedure is recommended to avoid confusing a boosted reaction with a true conversion.²¹⁶ The phenomenon of boosting can happen in a person who is infected but loses skin test reactivity after several years. In this situation, a single tuberculin test can be falsely negative, but the test itself can recall (i.e., boost) the waned reactivity. A subsequent test can then elicit a positive reaction. A positive reaction following a negative one may cause the person tested to be classified as a tuberculin converter. To elicit any potential boosted response and to categorize the person more accurately as infected or not infected, a second 5-TU tuberculin test is applied within 1 to 2 weeks of the first test. If the second test shows a positive reaction, it is interpreted as a boosted response indicative of prior infection; if the reaction remains negative, it is assumed to be truly negative.

The reaction to the test should be read by inspecting and palpating the area where the tuberculin was injected. The reaction size is determined by measuring the diameter of any induration with a ruler. The amount of erythema should not be taken into account; only the extent of induration is important. Readings must be recorded accurately in millimeters.

The interpretation of tuberculin tests requires clinical judgment, as well as an understanding of the test. In a population in which the only mycobacterial species causing infection is *M. tuberculosis*, the curve describing the distribution of reaction sizes in otherwise healthy infected persons given 5-TU PPD would be bell shaped, having a mode of 17 to 18 mm, with very few reactions less than 10 mm. Thus, defining the minimum reaction size indicative of tuberculous infection would be simple.²¹⁷ However, in many parts of the world, a portion of the population is infected with nontuberculous mycobacteria, which induce some degree of sensitization to tuberculin; inoculation with BCG, for many years the world's most commonly used vaccination, has the same enhancing effect on tuberculin reactivity. Although these reactions are on the whole smaller than those caused by *M. tuberculosis*, they blur the distinction between reactions in persons infected with *M. tuberculosis* and those not infected. On the basis of a large amount of epidemiologic data and skin testing with antigens prepared from nontuberculous mycobacteria, the best compromise between false-positive and false-negative readings to 5-TU PPD tuberculin tests is 10 mm. Thus, under most circumstances, a reading of 10 mm or more is considered indicative of infection with *M. tuberculosis*. However, in some situations, smaller reactions should be taken to indicate tuberculous infection. For example, a reaction of 5 mm in a child who is a contact of a person with smear-positive tuberculosis probably indicates tuberculous infection and is considered positive. Likewise, a 5-mm reaction in a person with known HIV infection should be considered positive. In the United States, the history of BCG administration is generally ignored in interpreting the results of the TST.²¹⁸

There are several reasons why the tuberculin reaction may be interpreted as negative in the presence of tuberculous infection. These include errors in application or reading of the test result, usually related to the inexperience of the tester/reader, and should be easily correctable with proper training. Problems with the antigen are infrequent unless it has been improperly handled. Many disease states, especially HIV infection, interfere with cell-mediated immune responses. Lymphoreticular malignancies such as Hodgkin disease are potent suppressors of cell-mediated immunity. Corticosteroids and immunosuppressive drugs decrease tuberculin reactivity if the patient is on a sufficient dose for a sufficient period of time; for corticosteroids, the minimum dose is 15 to 20 mg of prednisone or the equivalent of another preparation, given daily for 2 to 3 weeks.²¹⁹ As stated previously, advancing age is associated with loss of tuberculin reactivity, although it may be recalled.²¹⁵ Malnutrition also may cause defects in cell-mediated immunity with consequent diminished tuberculin reactivity. Finally, pleural tuberculosis and overwhelming tuberculosis itself may cause diminished or absent tuberculin responsiveness.

Even when the test is applied and the result is read with particular care in patients with proven tuberculosis and no apparent immunosuppression at the time they are admitted to a hospital, only 80% to 85% have reactions of 10 mm or more to 5-TU PPD.²²⁰ Thus, a negative tuberculin test result cannot be used to exclude tuberculosis as a diagnostic possibility.

The interpretation of the TST in persons with HIV infection is a particular problem because of the progressive immunosuppression in HIV disease. Individuals infected with HIV are less likely to have a positive tuberculin reaction. In a cross-sectional study of persons with HIV infection and a wide range of CD4⁺ lymphocyte counts, anergy—defined as lack of any reaction to tuberculin (5 TU) plus mumps and *Candida* antigens—was more common when the CD4⁺ count was less than 400 cells/ μ L.²²¹

INTERFERON- γ RELEASE ASSAYS

IFN- γ release assays (IGRAs) are used for the diagnosis of *latent tuberculous infection* (LTBI); these assays cannot distinguish LTBI from active tuberculosis. Two IGRAs are currently approved in the United States, the QuantiFERON-TB test and the T-SPOT.TB test. The QuantiFERON-TB (Qiagen, Alameda, CA) tests, specifically QuantiFERON-TB Gold and *QuantiFERON-TB Gold In-tube* (QFT-GIT), measure the amount of IFN- γ released from sensitized lymphocytes in whole blood incubated overnight with mixtures of *M. tuberculosis* antigens, ESAT-6 and CFP-10.²²² A newer-generation test includes an additional antigen, Tb7.7. The other approved test, the T-SPOT.TB, utilizes an ELISPOT format to quantify the number of cells in peripheral blood that secrete IFN- γ when stimulated with ESAT-6 and CFP-10 (Oxford Immunotec, Abingdon, United Kingdom).²²³

Neither the TST nor IGRAs have value for the diagnosis of active tuberculosis in adults. A systematic review and meta-analysis showed that the sensitivity to diagnose tuberculosis in low- and middle-income countries was 76% for T-SPOT.TB and 60% for QFT-GIT. The specificity was 61% and 52%, respectively.²²⁴

Compared with the TST, the IGRAs have several advantages: The tests can be performed in one patient visit, they are more specific in the presence of BCG vaccination or infection with nontuberculous mycobacteria, they are not subject to reader variability, and they do not stimulate waned immunity (the booster reaction, described earlier).²²³ A systematic review showed that IGRAs have excellent specificity and are not affected by BCG vaccination (due to the absence of ESAT-6 and CFP-10 from all strains of BCG).²²⁵ The sensitivity to diagnose infection (using culture-positive *M. tuberculosis* cases as the reference) was variable in the different studies, but T-SPOT.TB appeared to be more sensitive than QuantiFERON-TB Gold and QFT-GIT and the TST.^{225,226} In patients with HIV infection, the responses to TST and QFT-GIT correlate with the degree of immunodeficiency, whereas results of the T-SPOT.TB are independent of the level of CD4 T-cell depletion,²²⁷ which may explain the variable results of the different IFN- γ -release assays and TST among patients with HIV infection.²²⁸

IGRAs have a few disadvantages: The tests require drawing blood and processing it within a specific time, and they are less well known than the TST and, therefore, have much less evidence to characterize their performance for diagnosing latent tuberculous infection and for epidemiologic studies. For example, risk factors for conversion (from negative to positive) and reversion (from positive to negative) were different for T-SPOT.TB compared with the TST.²²⁹ The authors attributed these findings to a lack of understanding of the dynamics of the IFN- γ response to ESAT-6 and CFP-10. Also, because there is no knowledge about the time required for the IFN- γ release assays to become positive after the onset of infection, the interpretation of a negative IFN- γ release assay requires caution.

Other authors, who also found a substantial proportion of reversions, attributed their findings to the decrease of the bacterial load due to treatment and to the natural resolution of the infection.²³⁰ In a study in the United Kingdom, Wilkinson and colleagues,²³¹ using T-SPOT.TB, showed an early rise in spot-forming counts in patients given isoniazid and rifampin, then a reduction at month 3. No changes were observed in those without treatment. In India, Pai and colleagues²³² followed 216 nursing and medical students and observed that 9 (24%) of the 38 individuals with an initial positive QFT-GIT test had reversion, which was associated with a negative TST result. Interestingly, those with skin test conversion also had an increase in levels of IFN- γ . Taken together, these data underscore the uncertainty regarding the interpretation of the IFN- γ release assays in providing information about the outcome of infection with *M. tuberculosis*, both treated and untreated.

Currently, the U.S. Centers for Disease Control and Prevention (CDC) recommends using the QuantiFERON-TB Gold test for the same indications as the TST: for evaluating persons suspected of having tuberculosis and for screening, including contacts of an infectious case of tuberculosis, children younger than 17 years of age, pregnant women, and persons at increased risk of tuberculosis, particularly those with HIV infection, recent immigrants who have had BCG vaccination, and health care workers. The QuantiFERON-TB Gold test usually can be used in place of—and not in addition to—the TST.²³³

DIAGNOSIS OF PULMONARY TUBERCULOSIS

Currently, in the United States, 69% of new cases of tuberculosis involve the lungs only, 21% involve extrapulmonary sites only, and 10% involve both locations.²⁷ Although both miliary (disseminated) tuberculosis and pleural tuberculosis involve the lungs and/or pleural space, they are considered extrapulmonary forms of the disease.

DIAGNOSTIC EVALUATION

Clinicians must recognize that, in evaluating persons who may have tuberculosis, they are assuming an essential public health function and providing care to an individual patient. Early and accurate diagnosis is critical to tuberculosis care and control.²³⁴ Despite dramatically improved access to high-quality tuberculosis services worldwide during the past 2 decades, there is substantial evidence that failure to identify cases early is a major weakness in efforts to ensure optimal outcomes for the patient and to control the disease. Diagnostic delays result in ongoing transmission in the community and more severe, progressive disease in the affected person.

Globally there are three main reasons for delays in diagnosing tuberculosis: the affected person not seeking or not having access to care; the provider not suspecting the disease; and the lack of sensitivity of the most commonly available diagnostic test, sputum (or other specimen) smear microscopy.^{235,236} Approaches to reducing these delays are, obviously, quite different. Reducing delays on the part of the affected person entails providing accessible health care facilities, enhancing community and individual awareness, and active case finding in high-risk populations. Reducing provider delay is best approached by increasing provider awareness of the risks for and symptoms of tuberculosis and of the appropriate and available diagnostic tests. Rapid molecular tests that increase both the speed and the sensitivity for identifying *Mycobacterium tuberculosis* are increasingly available and, in some situations, are recommended by the WHO as the initial diagnostic test.

PATIENT HISTORY

There must be a clinical suspicion of tuberculosis before proper diagnostic tests are ordered. Clinical suspicion is prompted largely by the presence of symptoms and by awareness of comorbidities and epidemiologic circumstances that increase the risk of tuberculosis in an individual patient. These risks are summarized in the WHO guidelines for screening for tuberculosis.²³⁷ The most commonly reported symptom of pulmonary tuberculosis is persistent cough that generally, but not always, is productive of mucus and sometimes blood. In persons with tuberculosis, the cough is often accompanied by systemic symptoms, such as fever, night sweats, and weight loss. In addition, findings such as lymphadenopathy, consistent with concurrent extrapulmonary tuberculosis, may be noted, especially in patients with HIV infection. However, chronic cough with sputum production is not always present, even among

Figure 35-5 Aspergilloma developing in an old tuberculosis cavity. **A**, Front chest radiograph in a patient with tuberculosis shows bilateral upper lobe fibronodular changes with a right apical cavity (arrow). **B**, Frontal chest radiograph several years after (A) when the patient complained of hemoptysis shows development of an opacity within the right apical cavity (arrowheads) representing aspergilloma. **C-E**, Focused axial chest CT confirms the presence of aspergilloma. (Courtesy Michael Gotway, MD.)

persons with sputum smears showing acid-fast bacilli. Data from several tuberculosis prevalence surveys in countries with a high incidence of the disease show that an important proportion of persons with active tuberculosis do not have cough of 2 or more weeks, a criterion that, conventionally, has been used to define suspected tuberculosis.^{238,239} In these studies, 10% to 25% of patients with bacteriologically confirmed tuberculosis do not report cough. These data suggest that evaluation for tuberculosis, using a symptom review that includes cough of any duration, fever, night sweats or weight loss, may be indicated in selected risk groups, especially in areas where there is a high prevalence of the disease and in high-risk populations and individuals with increased susceptibility, such as persons with HIV infection. Use of this broadened set of questions in a population of persons with HIV infection was found to have a negative predictive value of 97.7% for tuberculosis.²⁴⁰ The presence of any one of the symptoms should be viewed as an indication for an evaluation for tuberculosis in high-risk groups or in high-incidence areas.

Hemoptysis is usually seen with more extensive involvement but does not necessarily indicate an active tuberculous process. Hemoptysis may also result from bronchiectasis left as a residual of healed tuberculosis; from rupture of a dilated vessel in the wall of an old cavity (*Rasmussen aneurysm*); from bacterial or fungal infection (especially in the form of a fungus ball [*aspergilloma* or *mycetoma*]) in an old residual cavity (Fig. 35-5); or from erosion of calcified lesions into the lumen of an airway (*broncholithiasis*).

The systemic features of tuberculosis include fever in approximately 35% to 80%, malaise, and weight loss; there may be a variety of hematologic abnormalities, especially leukocytosis and anemia.²⁴¹⁻²⁴³

PHYSICAL EXAMINATION

In most cases, physical findings are not particularly helpful. Crackles may be heard in the area of involvement, along with bronchial breath sounds, when lung consolidation is close to the chest wall. Amphoric breath sounds (like the

Figure 35-6 Primary tuberculosis. Frontal chest radiograph in a young adult shows superior segment right lower lobe consolidation associated with right hilar lymphadenopathy (arrow) due to primary *Mycobacterium tuberculosis* infection. Mild right paratracheal lymph node enlargement (arrowhead) is also visible. (Courtesy Michael Gotway, MD.)

low sound of blowing across the top of an open bottle) may be indicative of a cavity. Findings such as lymph node enlargement, suggestive of extrapulmonary tuberculosis, may also indicate concurrent pulmonary involvement.

RADIOGRAPHIC FEATURES

Radiographic examination of the chest is commonly the first diagnostic study undertaken, after the history and physical examination.^{244,245} However, in resource-limited settings, a chest radiograph is not necessarily included as part of the routine evaluation because of cost, complexity, and nonspecificity of the findings.

Pulmonary tuberculosis nearly always causes detectable abnormalities on the chest radiograph, although in patients with HIV infection, a chest radiograph may be normal in up to 11% of patients with positive sputum cultures.¹⁹⁶ In primary tuberculosis, resulting from recent infection, the process is generally seen as a middle or lower lung zone opacity, often associated with ipsilateral hilar adenopathy (Fig. 35-6). Atelectasis may result from compression of airways by enlarged lymph nodes. If the primary process persists beyond the time when specific cell-mediated immunity develops, cavities may form (so-called progressive primary tuberculosis).

Tuberculosis that develops at a time remote from the original infection (endogenous reactivation) usually involves the upper lobes of one or both lungs. Cavitation is common in this form of tuberculosis. The most frequent sites are the apical and posterior segments of the right upper lobe (Fig. 35-7) and the apical-posterior segment of the left upper lobe. Healing of the tuberculous lesions usually results in development of a fibrotic scar with shrinkage of the lung parenchyma and, often, calcification. Involvement of the anterior segments alone is unusual. In the immunocompetent adult with tuberculosis, intrathoracic adenopathy is uncommon. When the disease progresses, infected material may be spread via the airways

Figure 35-7 Cavitary tuberculosis. Frontal chest radiograph in a patient with tuberculosis shows extensive right upper lobe cavitation. (Courtesy Michael Gotway, MD.)

(i.e., "bronchogenic" spread) into the lower portions of the involved lung or to the other lung. Erosion of a parenchymal focus of tuberculosis into a blood or lymph vessel may result in dissemination of the organism and a miliary pattern on the chest imaging (Fig. 35-8, see Fig. 18-25). Radiographic findings in HIV-infected patients are affected

Figure 35-9 Tuberculosis in an HIV patient. Frontal chest radiograph in a patient with tuberculosis shows bilateral hilar lymph node enlargement (arrows) associated with poorly defined parenchymal nodular opacities (arrowheads) and nodular areas of consolidation (double arrowheads). (Courtesy Michael Gotway, MD.)

by the degree of immunosuppression. As further explained and illustrated in Chapter 90, tuberculosis relatively early in the course of HIV infection tends to produce typical radiographic findings with predominantly upper lobe infiltration and cavitation.²⁴⁶ With more advanced HIV disease, the radiographic findings become more “atypical”: cavitation is uncommon, and lower lung zone or diffuse opacities and intrathoracic adenopathy are frequent (Fig. 35-9). Surprisingly, a substantial number of HIV-infected patients with pulmonary tuberculosis had normal radiographs at the end of their course of treatment.²⁴⁷

The activity of a presumed tuberculous process cannot be determined simply from a single radiographic examination of the chest. A cavity might be a sterile residual of an old infection, whereas a fibrotic-appearing lesion may be active. Conversely, not all radiographic worsening of the residua of prior tuberculous lesions can be ascribed to reactivation of the disease, although such worsening should always be of concern. Superimposed infections with other organisms or bleeding from bronchiectasis or from residual cavities may cause new infiltrations to appear. In addition, carcinomas may arise from within the area of scarring (so-called scar carcinomas) and be the cause of radiographic changes.

From this discussion, it should be obvious that the chest radiograph, although extremely valuable, cannot provide a definitive diagnosis of tuberculosis. Because of the radiographic similarities among the other disorders in the differential diagnosis, and because of the uncertainties in assessing disease activity and in determining the reasons for progressive radiographic changes, careful microbiologic evaluation is always indicated. A nondiagnostic microbiologic evaluation should prompt a careful assessment for other causes of the radiographic abnormality.

BACTERIOLOGIC EVALUATION

As noted previously, a definitive diagnosis of tuberculosis can be established only by isolation of tubercle bacilli in

culture or by identification of specific nucleic acid sequences. When the lung is involved, sputum is the initial specimen of choice. Two sputum specimens should be collected, which can be obtained the same day because the sensitivity of tests using same-day specimens is similar to tests using specimens collected on different days.²⁴⁸ The collection of the sputum in 1 day allows results to be available the same day, thereby increasing the efficiency of sputum smear microscopy.²⁴⁸ The strategies for same-day microscopy include the preparation of 2 or 3 slides from sputum samples obtained the first day the patient is assessed. Collecting more than two sputum specimens increases the yield only slightly.²⁴⁹

There are several options for obtaining specimens from patients who are not producing sputum. The first and most useful in terms of yield and avoidance of patient discomfort is inducing sputum production by the inhalation of a hypertonic (3% to 5%) saline mist generated by an ultrasonic nebulizer. Sputum induced by this technique is clear and resembles saliva; thus, it must be properly labeled or it may be discarded by the laboratory. This is a benign and well-tolerated procedure, although bronchospasm may be precipitated in asthmatic patients.

Sampling of gastric contents via a nasogastric tube has a lower yield than sputum induction and is more complicated and uncomfortable for the patient. However, in children and some adults, gastric contents may be the only specimen that can be obtained. Gastric lavage should be performed early in the morning before the patient has gotten out of bed, eaten, or performed dental hygiene. Once the specimen is obtained, the specimen should be sent to the laboratory and processed the same day. To prolong the viability of the bacteria, neutralization of gastric acid with an equal volume of sterile 1% sodium bicarbonate is recommended when the specimen is not processed immediately.^{250,251}

Depending on the clinical circumstances, if the sputum is negative or cannot be obtained, the next diagnostic step is usually fiberoptic bronchoscopy with bronchoalveolar lavage, and in some instances transbronchial lung biopsy. The yield of bronchoscopy is high in miliary tuberculosis and in focal disease as well. Bronchoscopic procedures have been especially helpful in the diagnostic evaluations of patients with HIV infection with negative sputum smear microscopy.²⁵² Needle aspiration biopsy may also provide specimens from which mycobacteria are isolated, but the technique is especially suited to the evaluation of peripheral nodular lesions for which there is a suspicion of malignancy.

In some situations, a therapeutic trial of antituberculosis chemotherapy may be indicated before more invasive studies are undertaken. For example, a radiographic abnormality consistent with tuberculosis in a person who is younger than 40, is a nonsmoker, and comes from a country where there is a high prevalence of tuberculosis, either current or past tuberculosis is much more likely than a neoplasm, even in the presence of negative smears and cultures of sputum. In such a patient, improvement in the chest radiograph concomitant with antituberculosis treatment would be sufficient reason for making a diagnosis of tuberculosis and continuing with a full course of therapy. A response should be seen within 2 months of starting treatment. If no improvement is noted, the abnormality

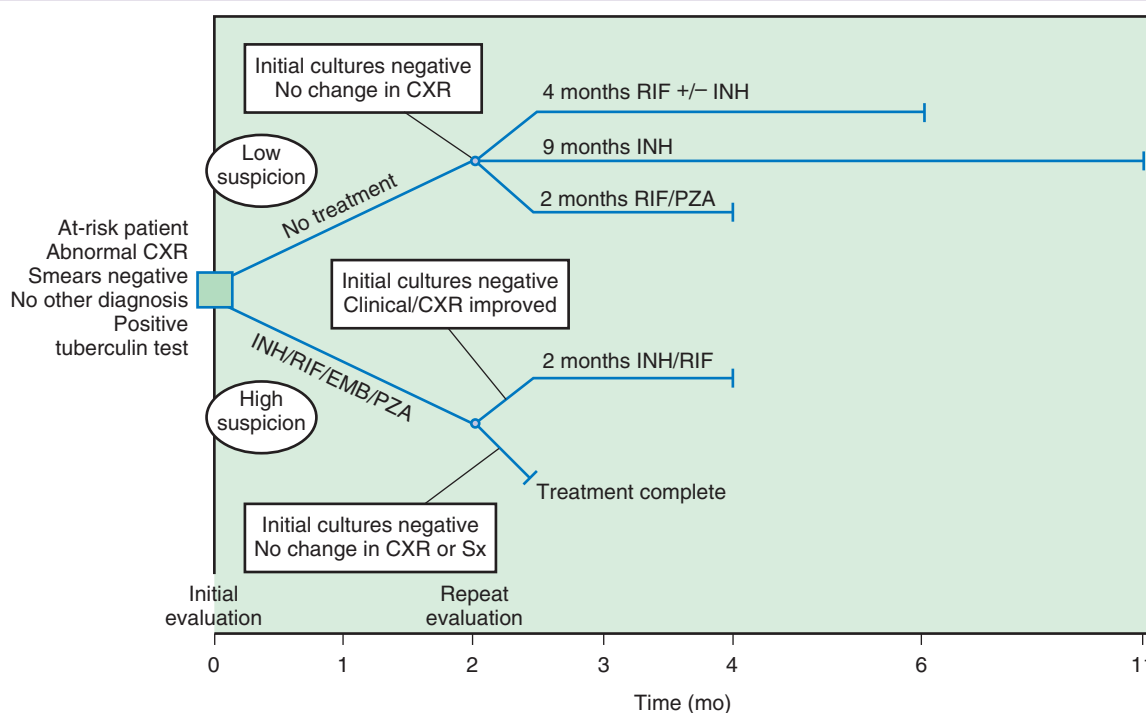

Figure 35-10 Treatment algorithm for active, culture-negative pulmonary tuberculosis and inactive tuberculosis. The decision to begin treatment for a patient with sputum smears that are negative depends on the degree of suspicion that the patient has tuberculosis. If the clinical suspicion is high (lower portion of figure), then multidrug therapy should be initiated before acid-fast smear/culture results are known. If the diagnosis is confirmed by a positive culture (see Fig. 35-11), treatment can be continued to complete a standard course of therapy. If initial cultures remain negative and treatment has been with multiple drugs for 2 months, then there are two options depending on repeat evaluation at 2 months (lower portion of figure). In option 1, if the patient demonstrates symptomatic or radiographic improvement without another apparent diagnosis, then a diagnosis of culture-negative tuberculosis can be inferred. Treatment should be continued with isoniazid and rifampin for an additional 2 months. In option 2, if the patient demonstrates neither symptomatic nor radiographic improvement, then tuberculosis is unlikely and treatment can be stopped. In low-suspicion patients not initially on treatment (upper portion of figure), if cultures remain negative, the patient has no symptoms, and the chest radiograph is unchanged at 2 to 3 months, there are three treatment options: (1) isoniazid for 9 months; (2) rifampin with or without isoniazid for 4 months; or (3) rifampin and pyrazinamide for 2 months. (See later discussion of latent tuberculous infection.) CXR, chest radiograph; EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; Sx, symptoms. (From Blumberg HM, Burman WJ, Chaisson RE, et al, for the American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: Treatment of tuberculosis. *Am J Respir Crit Care Med* 167:603–662, 2003.)

must be the result of either old tuberculosis or another process. An algorithm illustrating this approach is shown in Figure 35-10.

Because of the potentially disastrous consequences of delays in diagnosis of tuberculosis, it is essential that tests for *M. tuberculosis* be performed rapidly and the results be reported promptly. Waiting days for the results of microscopic examinations, weeks for culture results, and months for speciation and susceptibility studies is not acceptable.

Acid-Fast Staining

The first step in the diagnostic sequence is nearly always staining and examining readily available specimens for AFB. (See below for recommendations for use of rapid molecular tests in the initial evaluation). Finding AFB is generally specific for mycobacteria but provides no information about species. However, the sensitivity of microscopic examination is relatively low; the level of detection is approximately 10,000 bacilli per milliliter of secretions if 100 oil immersion microscopic fields are examined. The sensitivity of sputum smear microscopy can be increased by concentrating the sample either by centrifugation or sedimentation preceded by chemical processing.²⁵³ Sensitivity

can also be increased by about 10% using a fluorochrome staining procedure with auramine O, a fluorescent stain²⁵⁴ (see Fig. 35-1). This procedure requires use of a fluorescent microscope, which requires an excitation light source. There are two types of light sources. The first one is the short-arc *mercury vapor lamp* (MVP) which has a limited lifespan (200 to 300 hours), is costly, requires high maintenance, and is potentially toxic due to its mercury content. The second is the *light-emitting diode* (LED) that has a life span of more than 50,000 hours, is less expensive, and has a performance similar to the MVP-based microscopy.²⁵⁵ Fluorochrome-based procedures are faster than acid-fast staining because the intensity and contrast of the fluorescent signal on a dark background enables slides to be scanned at lower magnification (see Fig. 35-1).

Smears are generally interpreted as negative or, if positive, are reported as rare (3 to 9 organisms per slide), few (10 or more per slide), or numerous (1 or more per high-power oil immersion field). In most situations in which acid-fast organisms are detected by microscopy, they should be assumed to be *M. tuberculosis* until proven otherwise. Assuming the patient has tuberculosis will trigger the appropriate prompt responses from the physicians

responsible for treatment and from public health agencies. In practice, the sensitivity of sputum smears varies widely: 20% to 80% of patients with *M. tuberculosis* isolated in culture have positive smears.²⁵³

Mycobacterial Culture

Culture in liquid media is considered the current diagnostic gold standard and can detect as few as 10 to 1000 viable mycobacteria/mL. Culture is an essential step for diagnosis and is necessary for phenotypic drug susceptibility testing. Culturing mycobacteria from clinical specimens requires a higher level of technical capability than that needed for microscopy. The need for biosafety conditions, constant-temperature incubators, and a constant power supply restricts the use of culture in many low-resource settings. Culture of sputum usually involves digestion, decontamination, and concentration of the specimen before inoculation of media. This process decreases bacterial overgrowth and, when solid media are used, enables more uniform plating of the specimen. For specimens other than sputum, digestion and decontamination are not required. At a minimum, laboratories performing culture should be able to identify *M. tuberculosis*. Isolates that are not *M. tuberculosis* or are of questionable identity should then be sent to a more specialized laboratory for definitive speciation.

Culture can be performed in solid or liquid media. Solid media are usually less expensive and allow the morphologic examination of the colonies to be used for presumptive species identification. However, results on solid media are delayed due to the slow growth of mycobacteria and, in some settings, the delayed culture results may have limited or no impact on patient management.²⁵⁶ The solid media can be based on egg such as *Lowenstein-Jensen* (LJ) media or on agar such as Middlebrook 7H10 or 7H11 media. *M. tuberculosis* colonies appear in 2 to 8 weeks, and cultures without growth at 8 weeks are reported as negative, although they are generally kept for another 2 to 4 weeks before being discarded, as some strains grow more slowly than the average.

Liquid media are more sensitive and increase the yield by 10%. They enable *M. tuberculosis* growth to be detected in 10 to 14 days. However, liquid media also have a higher rate of contamination with other bacteria or with nonmycobacteria.²⁵⁷ The growth of *M. tuberculosis* in liquid media produces fluorimetric or colorimetric reactions, which are detected using manual or automated systems. The automated systems permit a higher throughput and should be used in settings with high workloads, especially for drug susceptibility testing. The manual systems are less expensive and are used in areas with limited resources.

***M. tuberculosis* Identification.** The methods to identify *M. tuberculosis* can be classified as (1) phenotype methods that include biochemical tests and specific cell and colony characteristics and (2) molecular-based methods that target *M. tuberculosis* complex-specific nucleic acids or proteins.

PHENOTYPE-BASED IDENTIFICATION METHODS. The classical phenotype-based methods to identify *M. tuberculosis* complex require a positive culture for mycobacteria. These tests include niacin production, nitrate reduction, and inactivation of catalase at 68° C. The tests also use the time to growth, which is usually 12 to 42 days in solid media; the

presence of rough, cauliflower-like, and colorless colonies; and the presence of organisms that are tangled and form corded masses when observed using a microscope.

The *microscopic observation of drug susceptibility* (MODS) assay is a culture-based method that discriminates between *M. tuberculosis* complex and nontuberculous mycobacteria and determines the drug susceptibility to rifampin and isoniazid at the same time. MODS incorporates the antituberculosis drugs in the culture media at the beginning of the assay. The method uses a sealed 24-well tissue-culture plate with liquid culture media containing different antibiotics and controls that are examined periodically under an inverted light microscope. *M. tuberculosis* can be identified by the observation of a tangled or a corded mass of organisms and by a time to detection (including susceptibility test), typically less than 2 weeks. When compared with traditional solid or liquid culture, the overall pooled sensitivity of MODS to detect *M. tuberculosis* growth was 92% and the specificity was 96% compared with conventional culture. The mean time from receipt of specimen to results was 9.2 days, and contamination was present in 7%.²⁵⁸ There is currently a MODS kit commercially available.

MOLECULAR-BASED IDENTIFICATION METHODS. Several molecular methods are available to identify *M. tuberculosis* directly on the specimen or in mycobacterial culture. They are based on *nucleic acid amplification technologies* (NAATs) in which as few as 1 to 10 copies of DNA or ribonucleic acid specific to *M. tuberculosis* complex are amplified to detectable levels. Other targets include proteins specific to *M. tuberculosis*. All these tests identify the presence of *M. tuberculosis* complex and can rule out the presence of nontuberculous mycobacteria. Importantly, some of these methods identify drug resistance-associated mutations in the same test. There are several commercial technologies, although only one, the GenProbe *Amplified M. tuberculosis Direct* test (AMTD), is available in the United States. The current recommendation by the CDC is to use an NAAT on at least one specimen, preferably the first diagnostic specimen from each patient in whom a TB diagnosis is being considered.²⁵⁹ The recommended interpretation algorithm includes the use of clinical judgment when the nucleic acid amplification test is negative. This limitation has been applied because it has been found that the sensitivity of the tests is not sufficiently high to exclude *M. tuberculosis*.^{259,260}

A major breakthrough in NAAT has been the development of an automated, self-contained, real-time *polymerase chain reaction* (PCR) assay to detect *M. tuberculosis* complex and rifampin resistance-associated mutations directly in clinical specimens (Xpert MTB/RIF).²⁶¹ This system is based on the amplification of a sequence of the *rpoB* gene specific to members of the *M. tuberculosis* complex and the rifampin resistance-determining region. It can be used directly on clinical specimens or specimens that have been digested and decontaminated.²⁶² It requires minimal biosafety measures²⁶³ and minimal hands-on technical time.²⁶⁴ It consists of two main components: (1) a disposable cartridge that contains sample processing and the *M. tuberculosis*-specific real-time PCR reagents and (2) an instrument that controls the fluidics in the cartridge and performs the PCR analysis.²⁶¹ The operational challenges are related to the specific needs of the components: Cartridges require a temperature below 28° C and have a 12-month shelf-life, and the

instrument requires a stable electrical power supply and an ambient temperature below 30°C.²⁶⁴ A meta-analysis showed that, as an initial test replacing smear microscopy, Xpert MTB/RIF pooled sensitivity was 89% and pooled specificity 99%.²⁶⁵ As an add-on test following a negative smear microscopy result, Xpert MTB/RIF pooled sensitivity was 67% and specificity 99%. For smear-positive, culture-positive TB, Xpert MTB/RIF pooled sensitivity was 98%. For people with HIV infection, Xpert MTB/RIF pooled sensitivity was 79% and, for people without HIV infection, it was 86%. The pooled sensitivity to detect rifampin resistance was 95%, and the pooled specificity was 98%.²⁶⁵ This assay has a median time to detection of *M. tuberculosis* of hours compared with 1 day for microscopy, 16 days for culture in liquid media, and 30 days for culture on solid media. The median time to detection of rifampin resistance with the automated and self-contained real-time PCR assay was 1 day compared with 106 days for phenotypic tests.²⁶⁶ More importantly, Xpert MTB/RIF reduced the median time to treatment of patients with sputum smear-negative tuberculosis from 56 days to 5 days.²⁶⁶ On the basis of its diagnostic accuracy, WHO endorsed the Xpert MTB/RIF for the diagnosis of tuberculosis in 2010.^{267,268} WHO is recommending that, for all patients (including children) who are suspected of having pulmonary tuberculosis and are capable of producing sputum, a single specimen submitted for Xpert MTB/RIF testing can be used as the initial test in place of two specimens submitted for smear microscopy. In addition, WHO recommends that Xpert MTB/RIF should be used as the preferred initial test for patients who are at risk for drug resistance, who have HIV risks, or who are seriously ill; because of the speed of diagnosis, the test is also preferred for use with cerebrospinal fluid in patients suspected of having tuberculous meningitis.

Other commercially available molecular methods can be used directly on clinical samples or mycobacterial cultures for identification of the *M. tuberculosis* complex and drug resistance-associated mutations on the same day the specimen is received.²⁶⁹ However, these technologies require more technical expertise and a more complex laboratory infrastructure. The line probe assay uses a DNA strip test that allows the simultaneous identification of *M. tuberculosis* and common genetic mutations causing resistance to isoniazid and rifampin from smear-positive sputum samples or from positive cultures. Currently, three line probe assays exist: the INNO-LiPARif.TB assay (Fujirubio, Europe, N.V.),²⁷⁰ which is available for research use only for the detection of *M. tuberculosis* and rifampin resistance, and two versions of the GenoTypeMTBDR assay (Hain Life-Science GmbH, Nehren, Germany). The GenoTypeMTBDR plus detects *M. tuberculosis* and rifampin and isoniazid resistance,²⁷¹ and the GenoTypeMTBDRsl detects the most common mutations in the *gyrA* gene for fluoroquinolone resistance; in the *rrs* gene for amikacin, capreomycin, and kanamycin resistance; and in the *embB* gene for ethambutol resistance.²⁷² The sensitivity of the INNO-LiPARif.TB for detecting rifampin resistance in culture isolates was greater than 95%, and the specificity was 100%.²⁷⁰ A meta-analysis for the performance of the GenoTypeMTBDR showed a pooled sensitivity of 98.1% and specificity of 98.7% for rifampicin resistance and a lower sensitivity of 84.3% and specificity of 99.5% for isoniazid.²⁷¹ Meta-analysis

for the performance of the MTBDRsl was as follows: for fluoroquinolone sensitivity—87.4%, specificity—97.1%; amikacin sensitivity—82.6%, specificity—99.5%; capreomycin sensitivity—82%, specificity—97.3%; kanamycin sensitivity—44.4%, specificity—99.3%; and ethambutol sensitivity—67.9%, specificity—79.9%.²⁷² In 2008, WHO endorsed the line-probe assays for the rapid detection of first-line drug resistance in low- and middle-income settings.²⁷³

Serologic Tests

Several antigens, including highly purified and recombinant antigens specific for *M. tuberculosis* complex, have been used in serologic antibody tests with variable results. A systematic review found that the results of serologic tests are highly variable and not better than sputum smear microscopy.²⁷⁴ On the basis of these results, WHO has strongly recommended against the use of serologic tests for the diagnosis of pulmonary and extrapulmonary tuberculosis.²⁷⁵

Drug Susceptibility Testing

Determination of susceptibility to antimicrobial agents is of considerable clinical importance. Because of concerns regarding tuberculosis caused by drug-resistant organisms, drug susceptibility testing is recommended for all initial *M. tuberculosis* isolates. Unfortunately, due to lack of resources, drug susceptibility testing is not done in most high-burden areas or is limited to *M. tuberculosis* strains isolated from patients at high risk of having drug-resistant tuberculosis (see Table 35-3). There are two general methods for determining resistance: phenotypic and genotypic.²⁷⁶ Some of the methods are designed to identify *M. tuberculosis* and determine the drug susceptibility in the same test, such as MODS, Xpert MTB/RIF and line probe assays, all of which were reviewed in the previous section on *M. tuberculosis* identification.

The *phenotypic methods* are based on culture of *M. tuberculosis*. There are two methods: absolute and proportional. These can be done in liquid or solid media. The reference standard is the proportion method, and it is recommended in liquid media. The proportional methods involve inoculating one or more dilutions of cultured mycobacteria on drug-free media and on media containing appropriate concentrations of antituberculosis drugs. Resistance is generally considered to be present when the growth on the drug-containing medium is 1% or more of the control growth on the drug-free media.

There are several approaches to detect mycobacterial growth.²⁷⁷ The colorimetric method is based on the reduction of an oxidation-reduction indicator (i.e., Alamar Blue, resazurin, or tetrazolium) added to the culture media after the cells of *M. tuberculosis* are exposed to the antibiotic. Resistance to antibiotics is identified by the presence of a change in color in the media due to the oxidation/reduction process by viable mycobacteria. This method is highly sensitive and specific for the detection of rifampin and isoniazid resistance (98% and 97% sensitive, respectively; 99% and 98% specific, respectively) when compared with conventional culture-based drug susceptibility methods.^{276,278} The nitrate reductase assay is based on the ability of *M. tuberculosis* to reduce nitrate to nitrite, which is also detected by a

color reaction. The sensitivity of the test was 97%, and the specificity was 100% for the detection of rifampin resistance and 97% and 99%, respectively, for detection of isoniazid resistance.^{276,278}

Testing for susceptibility to isoniazid and rifampin is accurate,²⁷⁸ and resistance to rifampin has been used as an indicator for multidrug-resistant tuberculosis.²⁷⁹ Testing for susceptibility to streptomycin, ethambutol, and pyrazinamide is less reliable and reproducible.²⁷⁸ Testing for second-line drugs is generally performed in reference laboratories and is recommended mainly for MDR strains. Testing for resistance to aminoglycosides, capreomycin, and fluoroquinolones is relatively accurate and reproducible, and the recommendation is to use the automated liquid culture systems.^{278,280} Testing for resistance to the other second-line drugs (ethionamide, prothionamide, cycloserine, terizidone, para-aminosalicylic acid, clofazimine, amoxicillin-clavulanate, clarithromycin, linezolid) is not standardized and not currently recommended.²⁷⁹

The *genotypic methods* to identify drug resistance are integrated with the *M. tuberculosis* identification methods; therefore, these methods are faster than culture-based tests. The genotypic methods are based on the detection of drug resistance–associated mutations: mutations in the *rpoB* rifampin resistance–determining region are present in 96% of rifampin-resistant strains,²⁸¹ mutations in *katG* or *inhA* in 65% to 75% of isoniazid-resistant strains,²⁸¹ and mutations in *gyrA* and *gyrB* in 42% to 85% of quinolone-resistant strains.^{281,282}

A common limitation of all genotypic methods is the inability to detect drug-resistant strains that do not harbor the common mutations. Therefore, it is essential to use conventional phenotypic methods to exclude drug-resistant tuberculosis.

There are several noncommercial genotypic methods. *Melting temperature (T_m)*-based assays utilize fully complementary strands of DNA that have higher melting temperatures than DNA with one or more nucleotide mismatches. This assay has been used together with “sloppy” molecular beacons to detect mutations in the rifampin resistance–determining region in a closed system minimizing cross-contamination.²⁸³ Other genotypic methods are based on sequencing genes or fragments of genes known to harbor drug resistance–associated mutations. Pyrosequencing, a rapid real-time method for sequencing small segments of genomic DNA, was successfully used to detect mutations in strains resistant to first- and second-line drugs.²⁸⁴

Another category of noncommercial methods is the bacteriophage-based assays, in which recombinant mycobacteriophage causes emission of light in the presence of live, but not dead (i.e., drug-killed), mycobacteria. These are promising, but several technical issues limit their use.²⁸⁵ The *phage-amplified biologic assay* (PhaB) can be used in sputum or mycobacterial culture to identify *M. tuberculosis* and drug-resistance mutations.²⁸⁶ The assays are relatively simple to use, they do not require extensive materials, and the results are available within 48 hours of processing. A meta-analysis demonstrated that, although these assays had good sensitivity, specificity was low and contamination was also a concern.^{285,287}

In spite of recent advances, none of the diagnostic methods is yet a point-of-care test, meaning that none of

the tests can now be used in clinics in resource-poor areas. Currently, the pipeline for such extremely rapid and simple tuberculosis diagnostics includes genotypic-based methods that could potentially be used at the patient's bedside. One group of assays is based on isothermal amplification technology that requires uniform incubation temperature (unlike PCR, which depends on a cyclical incubation temperature and requires complex equipment) utilizing simple technology that potentially could be used in peripheral laboratories where smear microscopy is performed. Loop-mediated isothermal amplification, where amplification products can be seen via fluorescence under ultraviolet light, is an example of this technology.²⁸⁸ Preliminary data showed that the loop-mediated isothermal amplification TB assay had comparable performance with other commercially available PCR-based assays used to identify *M. tuberculosis*²⁸⁸ and could potentially also identify drug-resistance mutations in the same reactions. Other point-of-care tests are based on the identification of *M. tuberculosis*–specific antigens such as *lipoarabinomannan* (LAM) using lateral flow immunochromatographic assays or strip tests to assay unprocessed urine. Unfortunately, its performance is low and its use is not recommended except for patients with advanced immunodeficiency due to HIV.²⁸⁹

PLEURAL TUBERCULOSIS

(see Chapter 80)

Although the pleural space is within the thorax, for reporting purposes it is considered an extrapulmonary site of tuberculosis. Tuberculous pleuritis accounts for 17% of the extrapulmonary cases in the United States.²⁷ The epidemiology of pleural tuberculosis parallels that of the overall pattern for tuberculosis, being more common among men and increasing in incidence with increasing age between 5 and 45 years. As noted previously, this epidemiologic pattern is modified by the presence of HIV infection, although pleural involvement seems less frequent among HIV-infected persons.

There are two mechanisms by which the pleural space becomes involved in tuberculosis. The difference in pathogenesis results in different clinical presentations, approaches to diagnosis, treatment, and sequelae. The first mechanism manifests early in the course of a tuberculous infection—a few tubercle bacilli may gain access to the pleural space and, in the presence of cell-mediated immunity, can cause a hypersensitivity response.^{290,291} This form of tuberculous pleuritis commonly goes unnoticed, and the process resolves spontaneously; those with resolved tuberculous pleuritis have a high likelihood of developing active tuberculosis in the next 2 years,²⁹² so tuberculous pleuritis should be considered and treated if found. However, in some patients, the tuberculous involvement of the pleura is manifested as an acute illness with fever and pleuritic pain.²⁹³ If the effusion is large enough, it may cause dyspnea, although the effusions are generally rather small and rarely bilateral.

The diagnosis of pleural tuberculosis is generally established by analysis of pleural fluid and by a pleural biopsy. In a patient with a pleural effusion that might be tuberculous, a diagnostic thoracentesis should be performed. Sufficient

fluid should be obtained for cell count, cytologic examination, biochemical analysis, and microbiologic evaluation (all described in detail in Chapter 79 and 80), but enough fluid should be left to allow a needle biopsy to be performed if the original specimen proves to be exudative and no diagnosis is evident. The fluid is nearly always straw colored, although it may be slightly bloody. Leukocyte counts are usually in the range of 100 to 5000 cells/ μ L.²⁹⁴ Early in the course of the process, polymorphonuclear leukocytes may predominate, but mononuclear cells soon become the majority. The fluid is exudative, with a protein concentration greater than 50% of the serum protein concentration, and the glucose level may be normal to low.

Adenosine deaminase has been shown to have high sensitivity, except in HIV-infected patients, but variable specificity, for diagnosing tuberculous pleural effusion.²⁹⁵ IFN- γ has been reported to have both high sensitivity (0.99) and high specificity (0.98) and to be equally reliable in HIV-infected and HIV-uninfected patients.^{296,297} Further studies are necessary to define the diagnostic role of this potentially useful test. Because few organisms are present in the pleural space, acid-fast smears of pleural fluid are rarely positive, and *M. tuberculosis* is isolated by culture in only 20% to 40% of patients with proven tuberculous pleuritis.^{293,298} A single closed-needle biopsy of the pleura with a Cope or an Abrams needle, with collection of three or four specimens for histologic examination, acid-fast staining, and culture of the tissue, confirms the diagnosis in approximately 65% to 75% of patients in whom tuberculous pleuritis is ultimately diagnosed. A second set of specimens in patients whose initial biopsy is negative increases the yield to 80% to 90%.²⁹⁸ The results of thoracoscopy are nearly always diagnostic, but the procedure is invasive, costly, and not always available. In a patient with an exudative mononuclear pleural effusion that remains undiagnosed after a full evaluation, including pleural biopsy, and who has a positive tuberculin reaction or IGRA result, antituberculosis treatment should be initiated.

Treatment of the hypersensitivity variety of tuberculous pleural effusion consists of standard antituberculosis drug regimens.²⁹⁹ Drainage via tube thoracostomy is rarely necessary, although repeat thoracenteses may be required to relieve symptoms. The use of corticosteroids may increase the rate of resolution and decrease the residual fluid, but such treatment is rarely indicated.³⁰⁰

The second variety of tuberculous involvement of the pleura, which is much less common than tuberculous pleurisy with effusion, is a true empyema that follows the spilling into the pleural space of a large number of organisms, usually from rupture of a cavity or an adjacent parenchymal focus via a bronchopleural fistula.³⁰¹ Tuberculous empyema is usually associated with evident pulmonary parenchymal disease on chest films. In this situation the fluid generally is thick and cloudy and may contain cholesterol, which causes the fluid to look like chyle (pseudochylous effusion). The fluid is exudative and usually has a relatively high white blood cell count, nearly all of which are lymphocytes. Acid-fast smears and mycobacterial cultures are usually positive, making pleural biopsy unnecessary.

In addition to standard antituberculosis chemotherapy, surgical drainage with an ordinary thoracostomy tube is

often necessary and may be required for a prolonged period of time. In selected patients who need ongoing drainage, creation of an Eloesser flap, in which a small portion of rib overlying the empyema space is resected and the skin is sutured to the pleura, is the procedure of choice.³⁰²

DISSEMINATED TUBERCULOSIS

Miliary tuberculosis, although it nearly always involves the lungs, is considered among the extrapulmonary forms of the disease because of the multiplicity of organs affected. The term *miliary* is derived from the similarity of the lesions to millet seeds. Grossly, these lesions are 1- to 2-mm yellowish nodules that on histologic examination are granulomas. In the past, miliary tuberculosis was mainly seen in young children, as an early consequence of initial infection and bacilleemia; currently, however, except among HIV-infected persons, it is more common among older persons, as a result of endogenous reactivation and bloodstream invasion. The shift in age-specific incidence presumably has been caused at least in part by the paucity of new infections in relation to the number of endogenous reactivations in the United States. The incidences in both sexes are nearly equal except in the HIV-infected population, in which the disease predominates among men.

Because of the multisystem involvement in disseminated tuberculosis, the clinical manifestations are protean. Initial screening laboratory studies are not particularly helpful. The chest radiograph, however, is abnormal in most but not all patients with disseminated tuberculosis: the frequency of a classic miliary pattern has ranged from 50% to 90%. Overall, it appears that, at the time of diagnosis, approximately 85% of patients have the diffuse tiny nodules characteristic of miliary tuberculosis. Other abnormalities may be present as well. These include upper lobe opacities with or without cavitation, pleural effusion, and pericardial effusion. As noted previously, HIV-infected patients may not be able to form granulomas; thus, instead of discrete individual lesions, a diffuse uniform pattern of infiltration may be seen.

Autopsy series have shown the liver, lungs, bone marrow, kidneys, adrenal glands, and spleen to be the organs most frequently involved in miliary tuberculosis, but any organ can be the site of disease.³⁰³ Because of the multiplicity of sites involved, there are many potential sources of material to provide a diagnosis. Acid-fast smears of sputum are positive in 20% to 25% of patients (even when the patient is not spontaneously coughing), and cultures of sputum are positive in 30% to 65%.³⁰⁴⁻³⁰⁶ In a patient with an abnormal chest radiograph and negative sputum examinations, bronchoscopy should be the next step. Combinations of bronchoalveolar lavage and transbronchial biopsy would be expected to have a high yield.³⁰⁷ Other potential sites for biopsy include liver and bone marrow, each of which has a high likelihood of showing granulomas (70% to 80%), but only a 25% to 40% chance of providing bacteriologic confirmation; urine cultures may be positive in up to 25% of patients.^{305,306} Selection of other potential sources of diagnostic material should be guided by specific findings.

The role of rapid nucleic acid amplification tests for identification of *M. tuberculosis* in patients with miliary

tuberculosis has not been defined, and neither of the two tests licensed by the U.S. Food and Drug Administration is approved for nonrespiratory specimens, although Xpert MTB/RIF is recommended for use with specimens from extrapulmonary sites by WHO.³⁰⁸ The reported data are difficult to interpret because, often, the results of specimens from different sites are combined, patients are selected by a variety of criteria, and test performance varies.³⁰⁹⁻³¹¹ In contrast, several studies have shown that Xpert MTB/RIF can provide rapid molecular diagnostic assessment when extrapulmonary tuberculosis is suspected. The growing body of literature, including two large studies, demonstrated a sensitivity of 81% and specificity of 99%.³¹²⁻³¹⁴

Before the era of chemotherapy, disseminated tuberculosis was uniformly fatal. With treatment, however, the reported case-fatality rates range from 29% to 64%.³⁰⁶ Meningeal involvement increases mortality and, when it is present, the duration of standard chemotherapy should be extended from 6 to 9 or 12 months, and corticosteroids may be useful to reduce mortality.³¹⁵

TREATMENT

Further information about the introduction and development of chemotherapy for pulmonary tuberculosis is provided in the [Appendix](#) for this chapter, which can be found online.

The Appendix also provides details about the mechanisms of action, genetic basis of resistance, and chief adverse effects of each of the main first- and second-line antituberculosis agents that are currently in use; also included is [Table 35A-1](#), which lists the available preparations and their recommended doses.

CURRENT STANDARD REGIMENS

The treatment regimens that are currently recommended by the American Thoracic Society, the CDC, and the Infectious Diseases Society of America and also by the WHO are shown in [Table 35-1](#).^{299,316} The recommended basic treatment regimen for previously untreated patients with pulmonary tuberculosis consists of an *initial* (or *intensive*) phase of isoniazid, rifampin, pyrazinamide, and ethambutol given for 2 months, followed by a 4-month *continuation* phase of isoniazid and rifampin. The initial phase rapidly reduces the bacterial burden, by killing the actively growing bacteria, while the continuation phase is protracted and intended to eliminate the subpopulation of bacteria that are replicating more slowly. The latter population is sometimes termed *drug tolerant*, meaning that the bacteria are not efficiently killed by drugs but have not acquired resistance mutations. As shown in [Table 35-1](#), there are several variations in the frequency of drug administration that are largely designed to enable health care personnel (or their surrogates) to provide closer supervision of treatment and produce acceptable results.^{299,316} Intermittent administration of antituberculosis drugs enables supervision to be provided more efficiently and economically with no reduction in efficacy, although daily administration provides a greater margin of safety. The evidence on effectiveness

of intermittent regimens has been reviewed.^{317,318} These reviews suggest that antituberculosis treatment may be given intermittently three times a week throughout the full course of therapy or twice weekly in the continuation phase without apparent loss of effectiveness except among individuals with advanced HIV infection.^{317,319-321} However, the WHO does not recommend the use of twice-weekly intermittent regimens because of the potentially greater consequences of missing one of the two doses.

Several caveats apply to these recommendations for treatment to be successful. First, the organisms must be susceptible to the drugs used. Because of concerns with drug resistance, initial isolates from patients with tuberculosis should have drug susceptibility tests performed and the results should be used to guide treatment. Second, patients must take all or nearly all of the prescribed treatment. Third, success should be documented by bacteriologic evaluation; that is, sputum cultures should be negative by the end of 3 months of treatment. If the sputum still contains *M. tuberculosis* after 3 months of therapy, the patient should be reassessed carefully to determine whether a change in treatment is necessary. The assessment should include a review of adherence, and evaluation for any comorbidities that might interfere with response. After 3 months of chemotherapy, more than 90% of patients taking regimens containing isoniazid and rifampin should have negative sputum cultures. Failure of the sputum to become negative generally means that either the organisms are resistant to the agents being used or the patient is not taking the drugs. Patients who continue to have *M. tuberculosis* in their sputum after 3 months of treatment should be started on directly observed therapy, if not already being supervised, and should have drug susceptibility testing performed by phenotypic methods or a rapid molecular test. If resistance is found, the regimen should be modified accordingly. If sputum samples are still positive after 4 months of therapy, the regimen should be considered a failure and a new regimen should be begun, ideally based on recent drug susceptibility test results. A list of possible regimens for non-MDR drug resistant tuberculosis (strains resistant to one or more drugs, excluding those with combined isoniazid and rifampin resistance) is shown in [Table 35-2](#).

The recommendation of a four-drug intensive phase is based, in part, on findings of the British Medical Research Council that revealed the need for a regimen that would be effective in the presence of isoniazid resistance; the inclusion of ethambutol during the intensive phase lessens the likelihood of selecting for rifampin resistance in strains with primary isoniazid resistance.³²²⁻³²⁴ Several factors have been found to be predictive of a poor therapeutic outcome, including extensive tuberculosis and a large population of bacilli, the rapidity or slowness with which sputum becomes negative after treatment is begun, and several factors associated with adherence.^{299,320,325,326} In U.S. Public Health Service Study 22, the presence of cavitation on the initial chest film and sputum culture positivity at the end of the 2-month intensive phase of treatment were highly predictive of an adverse outcome—either treatment failure or relapse.³²⁰ For this reason, in patients with cavitation on the initial chest film and who have positive sputum cultures at the end of the initial phase of treatment, prolongation of

Further information about the introduction and development of chemotherapy for pulmonary tuberculosis is provided in the [Appendix](#) for this chapter.

Table 35-1 Drug Regimens for Culture-Positive Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms

INITIAL PHASE			CONTINUATION PHASE			
Regimen	Drugs	Interval and Doses* (Minimum Duration)	Regimen	Drugs	Interval and Doses*† (Minimum Duration)	Range to Total Doses (Minimum Duration)
1	INH RIF PZA EMB	7 days/wk for 56 doses (8 wk) or 5 days/wk for 40 doses (8 wk)‡	1a	INH/RIF	7 days/wk for 126 doses (18 wk) or 5 days/wk for 90 doses (18 wk)§¶	182-130 (26 wk)
			1b§	INH/RIF	Twice weekly for 36 doses (18 wk)	92-76 (26 wk)
			1c¶	INH/RPT	Once weekly for 18 doses (18 wk)	74 or 58 (26 wk)
2	INH RIF PZA EMB	7 days/wk for 14 doses (2 wk) then twice weekly for 12 doses (6 wk) or 5 days/wk for 10 doses (2 wk)‡ then twice weekly for 12 doses (6 wk)	2a§	INH/RIF	Twice weekly for 36 doses (18 wk)	62-58 (26 wk)
			2b¶	INH/RPT	Once weekly for 18 doses (18 wk)	44 or 40 (26 wk)
3	INH RIF PZA EMB	Thrice weekly for 24 doses (8 wk)	3a	INH/RIF	Thrice weekly for 54 doses (18 wk)	78 (26 wk)
4	INH RIF EMB	7 days/wk for 56 doses (8 wk) or 5 days/wk for 40 doses (8 wk)‡	4a	INH/RIF	7 days/wk for 217 doses (31 wk) or 5 days/wk for 155 doses (28 wk)‡	273-195 (39 wk)
			4b§	INH/RIF	Twice weekly for 62 doses (31 wk)	118-102 (39 wk)

*When *directly observed therapy* (DOT) is used, drugs may be given 5 days/wk and the necessary number of doses adjusted accordingly. Although there are no studies that compare 5 with 7 daily doses, extensive experience indicates this would be an effective practice.

†Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 mo of therapy should receive a 7-mo (28-week; either 196 doses [daily] or 56 doses [twice-weekly]) continuation phase.

‡Five-day-a-week administration is always given by DOT.

§Options 1b, 2a, 4b are not recommended for HIV-infected patients with CD4⁺ cell counts less than 100 cells/μL.

¶Options 1c and 2b should only be used in HIV-negative patients who have negative sputum smears at the time of completion of 2 mo of therapy and who do not have cavitation on the initial chest radiograph (see text). For patients started on this regimen and found to have a positive culture at 2 mo, treatment should be extended an extra 3 mo.

EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine.

Modified from Blumberg HM, Burman WJ, Chaisson RE, et al, for the American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: Treatment of tuberculosis. *Am J Respir Crit Care Med* 167:604–662, 2003.

the continuation phase to 7 months, making a total of 9 months of treatment, is recommended. Factors that have been associated with poor clinic attendance and, therefore, with less chance of favorable response, include use of alcohol, younger age (but older than 18), and unmarried status. Patients with any of these characteristics should be monitored especially carefully. Although directly observed therapy (DOT) is labor intensive, the improved outcomes shown in retrospective analyses justify its use in preventing treatment failure and relapse, both of which have striking cost and public health consequences.

The algorithm shown in Figure 35-11 presents the approach to treatment of pulmonary tuberculosis in patients with *M. tuberculosis* isolated from sputum, and Figure 35-10 shows a treatment algorithm for patients with radiographic evidence of tuberculosis but negative bacteriologic examinations. In the absence of bacteriologic confirmation, treatment depends first on the degree of suspicion of active disease, and second on whether or not initial treatment causes clinical or radiographic improvement.

HIV Infection

The recommended treatment regimen for HIV-infected patients with tuberculosis consists of the same 6-month regimen as described for non-HIV-infected persons, but there are several important areas in which therapy may differ. Although, in general, rates of relapse are not increased among HIV-infected patients who take a standard 6-month regimen in the United States, there is an association with acquiring rifampin resistance.³²⁷⁻³²⁹ In sub-Saharan Africa, however, the likelihood of death, especially during the first 2 months of therapy, and of relapse following apparently successful treatment is higher in HIV-infected than in non-HIV-infected patients.³³⁰

The cause of rifampin monoresistance is not clear but has been associated with the use of once- or twice-weekly drug administration in the continuation phase and prior use of rifabutin as prophylaxis for *Mycobacterium avium* complex infections.^{321,327} For this reason, the rifapentine once-weekly regimen is contraindicated for all patients with HIV infection, and a twice-weekly regimen is not

Table 35-2 Selected Treatment Regimens for Non–Multidrug-Resistant Tuberculosis*

Resistance to	Treatment Regimen	Duration of Therapy	Comments
Isoniazid (± streptomycin)	Rifampin Ethambutol Pyrazinamide	6-9 mo	A fluoroquinolone may strengthen the regimen for patients with extensive disease.
Isoniazid and pyrazinamide	Rifampin Ethambutol Fluoroquinolone [†]	9-12 mo	A longer duration of treatment should be used for patients with extensive disease.
Isoniazid and ethambutol	Rifampin Pyrazinamide Fluoroquinolone	9-12 mo	A longer duration of treatment should be used for patients with extensive disease.
Rifampin	Isoniazid Ethambutol Fluoroquinolone plus at least 2 mo of pyrazinamide	12-18 mo	An injectable drug may strengthen the regimen for patients with extensive disease.
Rifampin and ethambutol (± streptomycin)	Isoniazid, pyrazinamide Fluoroquinolone plus injectable drug [‡] for at least the first 2-3 mo	18 mo	A longer course (6 mo) of the injectable may strengthen the regimen for patients with extensive disease.
Rifampin and pyrazinamide (± streptomycin)	Isoniazid Ethambutol Fluoroquinolone plus injectable drug for at least the first 2-3 mo	18 mo	A longer course (6 mo) of the injectable may strengthen the regimen for patients with extensive disease.
Isoniazid, ethambutol, pyrazinamide (± streptomycin)	Rifampin Fluoroquinolone plus an oral second-line agent, [§] plus injectable drug for at least the first 2-3 mo	18 mo	A longer course (6 mo) of the injectable may strengthen the regimen for patients with extensive disease.
Pyrazinamide	Isoniazid, rifampin plus at least 2 mo of ethambutol	9 mo	Most commonly seen in <i>M. bovis</i> infection.

*Strains resistant to one or more drugs, excluding combined isoniazid and rifampin resistance.

[†]Fluoroquinolones: levofloxacin or moxifloxacin.

[‡]Injectable drugs: streptomycin, amikacin, kanamycin, or capreomycin.

[§]Oral second-line drugs: ethionamide, cycloserine, or *p*-aminosalicylic acid.

From the Curry National Tuberculosis Center and California Department of Public Health, Drug-Resistant Tuberculosis: *A survival guide for clinicians*, ed 2. Sacramento, CA, 2008, California Department of Public Health, pp 34–35.

recommended for HIV-infected patients with CD4⁺ counts less than 100 cells/μL.²⁹⁹ An important concern in treating tuberculosis in patients with HIV infection is the potential for interactions with other drugs, especially antiretroviral agents, as discussed in detail in Chapter 90. Detailed, regularly updated recommendations for managing drug interactions during treatment of tuberculosis and HIV are available online (http://www.cdc.gov/tb/publications/guidelines/TB_HIV_Drugs/default.htm). The most practical means of minimizing the effects of interactions is to use a regimen consisting of two nucleoside reverse transcriptase inhibitors plus efavirenz or, in pregnant women, nevirapine in the HIV treatment regimen, and rifabutin in place of rifampin in the antituberculosis regimen. Monitoring of serum drug concentrations may be useful in avoiding the adverse consequences of the interactions. Current recommendations are that in persons with HIV infection and tuberculosis who have profound immunosuppression (CD4 counts < 50 cells/mm³), ART should be initiated within 2 weeks of beginning treatment for tuberculosis unless tuberculous meningitis is present. For all other patients with HIV and tuberculosis, regardless of CD4 counts, antiretroviral therapy should be initiated within 8 weeks of beginning treatment for tuberculosis. In part, the recommendation for antiretroviral treatment regardless of CD4 cell counts is because of the effect in reducing transmission of HIV.³³² The exception to this recommendation is in patients with tuberculous meningitis in whom immune reconstitution may have serious

consequences.³³³ The greatest benefit for reducing mortality in patients with tuberculosis and HIV infection is realized in those having CD4⁺ counts less than 200 cells/μL. For patients with higher CD4⁺ counts, the mortality benefit is less clear.³³⁴⁻³³⁶

Another feature of the treatment of tuberculosis, as well as of other opportunistic infections, is the paradoxical worsening that may be seen in HIV-infected persons who are also receiving antiretroviral therapy, a clinical phenomenon known as the *immune reconstitution inflammatory syndrome* (IRIS). The frequency of tuberculosis-related IRIS varies, depending on the case definitions used.^{333,337} Two main syndromes or forms of IRIS are associated with tuberculosis in persons with HIV infection.³³⁸ The more common syndrome is the paradoxical tuberculosis-associated IRIS that arises within the first weeks or months after the start of antiretroviral therapy in patients already being treated for tuberculosis. The second IRIS syndrome, known as *antiretroviral therapy-associated tuberculosis*, arises when tuberculosis (or some other lurking undiagnosed HIV-linked complication) is “unmasked” and flares up not long after beginning antiretroviral therapy. Characteristic features of both forms include new or exacerbated symptoms or signs of tuberculosis including worsening of pulmonary opacities, increasing pleural effusions, or increasing lymphadenopathy (Fig. 35-12). Usually, the syndrome is self-limiting, with a median duration of 2 months. Risk factors for the development of this form of IRIS include advanced HIV

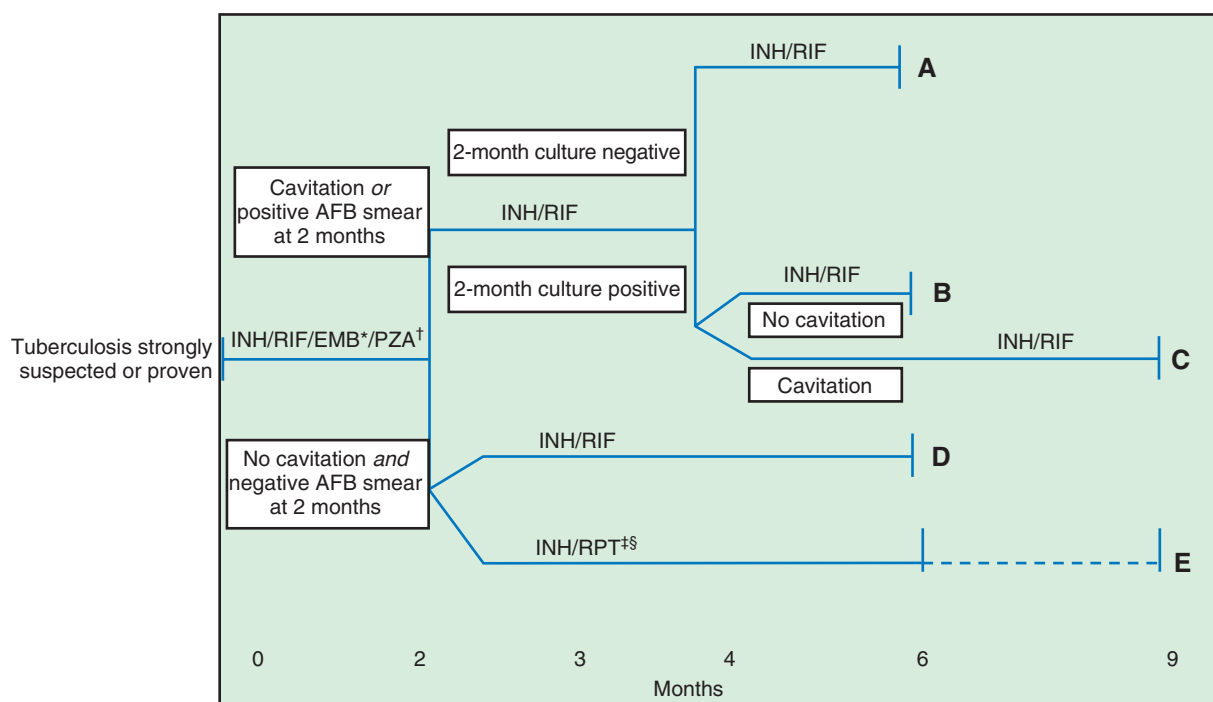

Figure 35-11 Treatment algorithm for patients with confirmed or strongly suspected tuberculosis. For patients in whom tuberculosis is confirmed or strongly suspected, the *intensive phase* of treatment should consist of isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months. The choice of regimen for the *continuation phase* depends on 3 factors: 1) the presence or absence of cavitation on the initial chest radiograph, 2) the culture status at the completion of the intensive phase of treatment (month 2), and 3) the presence or absence of advanced HIV infection. In patients without advanced HIV infection, if there is cavitation on the initial chest radiograph and the 2-month culture is positive, the continuation phase of treatment should consist of isoniazid and rifampin daily or twice weekly for 7 months to complete a total of 9 months of treatment. (**Arm C**) Otherwise the continuation phase should consist of isoniazid and rifampin daily or twice weekly for 4 months to complete a total of 6 months of treatment. (**Arms A, B, & D**) An additional option for patients without advanced HIV infection, who do not have cavitation on the initial radiograph and who have negative sputum smears at month 2, is a regimen consisting of isoniazid and rifapentine given once weekly. (**Arm E**) In this arm, if the 2-month culture becomes positive, the treatment is extended by an additional 3 months for a total of 9 months (*dashed line*). In patients with advanced HIV infection (CD4 counts of less than 100 cells/ μ l), the continuation phase should follow the same recommendations as above except that drug administration should be daily or three times weekly. Due to lack of efficacy, patients with advanced HIV should not have either twice weekly drug administration or the once weekly isoniazid-rifapentine regimen. *EMB may be discontinued when results of drug susceptibility testing indicate no drug resistance. †PZA may be discontinued after it has been taken for 2 months (56 doses). ‡RPT should not be used in HIV-infected patients with tuberculosis or in patients with extrapulmonary tuberculosis. §Therapy should be extended to 9 months if 2-month culture is positive. CXR, chest radiograph; EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine. (Modified from Blumberg HM, Burman WJ, Chaisson RE, et al, for the American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: Treatment of tuberculosis. *Am J Respir Crit Care Med* 167:603–662, 2003.)

Figure 35-12 Tuberculous lymphadenitis in a patient with immune reconstitution inflammatory syndrome (IRIS) after initiation of antiretroviral therapy. disease, disseminated and extrapulmonary tuberculosis, a short interval between starting antituberculosis and antiretroviral treatments, and a response to antiretroviral therapy as reflected by a decreased viral load.

Drug Resistance

The fourth Global Drug Resistance Surveillance Project conducted between 2002 and 2007 by the WHO and the International Union Against Tuberculosis and Lung Disease included more than 90,000 patients from 81 countries, representing 35% of the global notified new smear-positive cases.³³⁹ Drug resistance was found in all countries surveyed, with the exception of Iceland, with a weighted mean of 17% of new cases having resistance to at least one anti-tuberculosis drug and 2.9% having MDR (resistance to at least isoniazid and rifampin). According to the most recent WHO estimates, in 2012, approximately 450,000 new cases of MDR tuberculosis were identified worldwide. This estimate includes 3.6% of all new, never-treated patients and 20.2% of all previously treated patients.² The drug-resistance surveillance report found areas of the world in

which rates of MDR are truly alarming, such as Baku, Azerbaijan, where 56.3% of new cases were resistant to any drug and 22.3% were MDR, a considerable worsening since the previous report.³³⁹

In 2006, XDR tuberculosis—defined as tuberculosis caused by *M. tuberculosis* that is not only MDR but also resistant to any one of the fluoroquinolones and to at least one of three injectable second-line drugs (amikacin, capreomycin, or kanamycin)—was identified and rapidly recognized as a serious emerging threat to global public health.^{49,340} Subsequent reports have identified XDR tuberculosis in all regions of the world, with countries from the former Soviet Union reporting as high as 24% XDR tuberculosis among the MDR cases.² The two strongest risk factors for XDR tuberculosis are failure of a tuberculosis treatment regimen that contains second-line drugs, including an injectable agent and a fluoroquinolone, and close contact with an individual with documented XDR tuberculosis or with an individual for whom treatment with a regimen including second-line drugs is failing or has failed.

Drug resistance is largely man-made; a consequence of suboptimal regimens and treatment interruptions.³⁴¹ Clinical errors that commonly lead to the emergence of drug resistance include failure to provide effective treatment support and assurance of adherence; inadequate drug regimens; adding a single new drug to a failing regimen; and failure to recognize existing drug resistance. In addition, comorbid conditions associated with reduced serum levels of antituberculosis drugs (e.g., malabsorption, rapid transit diarrhea, use of antifungal agents) and interruptions caused by adverse drug reactions may also lead to the acquisition of drug resistance.³⁴² An additional potential source of drug resistance is substandard drugs, which may exist due to poor manufacturing or deterioration due to improper storage.³⁴³

Transmission of drug-resistant strains of *M. tuberculosis* has been well described in health care facilities, in congregate settings, and in susceptible populations, notably HIV-infected persons.^{173,344-347} However, MDR *M. tuberculosis* may spread in the population at large, as was shown in data from a number of countries, including China, the Baltic States, and countries of the former Soviet Union.^{339,348-350}

The strongest factor associated with drug resistance is previous antituberculosis treatment.³³⁹ In previously treated patients, the odds of any resistance are at least 4-fold higher, and that of MDR at least 10-fold higher, than in new (untreated) patients.³⁵¹ Patients with chronic tuberculosis (sputum-positive after retreatment) and those who fail treatment are at highest risk of having MDR tuberculosis, especially if rifampin was used throughout the course of treatment. Persons who are in close contact with confirmed MDR tuberculosis patients, especially children and HIV-infected individuals, also are at high risk of being infected with MDR strains. In some closed settings, prisoners, persons staying in homeless shelters, and certain categories of immigrants and migrants are at increased risk of MDR tuberculosis. These factors are summarized and presented in descending order of level of risk in Table 35-3.

Given the importance of drug resistance, both for the individual and for the community, all patients for whom treatment is being initiated should be assessed for their risk of having tuberculosis caused by drug-resistant organisms. The assessment should be based on history of prior treatment, exposure to a possible source case having drug-resistant organisms, and the community prevalence of drug resistance (if known). Whenever possible, the assessment should also include history of fluoroquinolone use in the period preceding diagnosis of tuberculosis because monotherapy with fluoroquinolones for as little as 10 days increases the incidence of fluoroquinolone-resistant *M. tuberculosis*.³⁵²⁻³⁵⁴ Although drug susceptibility testing

Table 35-3 Assessing Risk for Drug Resistance

Risk Factors for Resistance	Comments
Failure of retreatment regimen (a second course of treatment after failure, relapse, or default)	Patients who are still sputum smear positive at the end of a retreatment regimen have perhaps the highest drug-resistance rates of any group, often exceeding 80%.
Close contact with a known drug-resistant case	Tuberculosis in close contacts of drug-resistant TB patients is likely to be drug-resistant TB.
Failure of the initial treatment regimen	Patients who fail to become sputum smear negative while on treatment are likely to have drug-resistant organisms. However, the likelihood depends on a number of factors, including whether rifampicin was used in the continuation phase and whether DOT was used throughout treatment. Thus, a detailed history of drugs used is essential. This is especially true for patients treated by private providers, often with nonstandard regimens.
Relapse after apparently successful treatment	Most patients who relapse have fully susceptible organisms. However, under program conditions, an apparent relapse, especially an early relapse, may, in fact, be an unrecognized treatment failure and thus have a higher likelihood of drug resistance.
Return after default without recent treatment failure	The likelihood of drug resistant TB varies substantially in this group, depending in part on the duration of treatment and the degree of adherence before default.
Exposure in institutions that have drug-resistant TB outbreaks or a high drug-resistant TB prevalence	Patients who frequently stay in homeless shelters, prisoners in many countries, and health care workers in clinics, laboratories, and hospitals can have high rates of drug-resistant TB.
Residence in areas with high prevalence of drug-resistant TB	Drug-resistant TB rates in many areas of the world can be high enough to justify routine drug sensitivity testing in all new cases.

Modified from World Health Organization: Guidelines for the programmatic management of drug-resistant tuberculosis. WHO/HTM/TB/2008.402. www.who.int/tb/publications/2008/en/. Accessed July 8, 2014.

should be performed at the start of therapy for all patients, those who are at increased risk of drug resistance should be prioritized and a rapid molecular test (if available) should be performed. In addition, patients who remain sputum culture positive at completion of 3 months of treatment, patients in whom treatment has failed, and patients who have been lost to follow-up, or relapsed following one or more courses of treatment, should always be assessed for drug resistance.

Because of difficulties in the design of randomized controlled treatment trials for MDR/XDR tuberculosis using multidrug regimens, none has been conducted to evaluate currently available approaches to treatment. In the absence of clinical trial data, current recommendations for treating MDR/XDR tuberculosis are based on observational studies, general microbiologic and therapeutic principles, extrapolation from available evidence from pilot MDR tuberculosis treatment projects, and expert opinion.³⁵¹⁻³⁶²

More systematic guidance has been obtained from a carefully conducted individual patient meta-analysis that examined the outcomes of treatment for MDR tuberculosis and concluded that treatment success, compared with failure/relapse or death, was associated with use of later-generation fluoroquinolones, as well as ofloxacin, ethionamide or prothionamide, use of four or more likely effective drugs in the initial intensive phase, and three or more likely effective drugs in the continuation phase.³⁶³ In addition, not surprisingly, outcomes in patients with XDR tuberculosis are worse when there was resistance to additional drugs beyond those that comprise the definition of XDR.³⁶⁴

On the basis of available information, there are three treatment options for MDR/XDR tuberculosis: standardized, empiric, and individualized regimens. The approach is dependent on having an accurate history of prior treatment, reliable drug susceptibility testing results for individual patients, and/or population data on the prevalent resistance patterns. In general, in areas where drug susceptibility is widely available, individualized treatment regimens are used.

Current global recommendations are that patients with confirmed MDR tuberculosis should be treated with a regimen consisting of an intensive phase of 6 to 8 months containing at least five drugs: pyrazinamide and four drugs to which the organisms are known or presumed to be susceptible, including an injectable agent. The continuation phase should contain at least three drugs to which the organisms are known or presumed to be susceptible. The total treatment duration should be at least 18 to 24 months beyond culture conversion.³⁵¹ Patient-centered measures, including observation of treatment, are required to ensure adherence. Consultation with a specialist experienced in treatment of patients with MDR/XDR tuberculosis should be obtained.

On the basis of their activity, efficacy, route of administration, tolerance, availability, and costs, antituberculosis drugs can be classified in five groups.³⁵⁷ Group 1 consists of first-line drugs: isoniazid, rifampin, ethambutol, pyrazinamide, and rifabutin. Any of these drugs should be used if it is thought that susceptibility remains. Only one drug should be selected from Group 2 (injectable agents—kanamycin, amikacin, capreomycin, streptomycin) and Group 3 (fluoroquinolones) because of documented total

or partial cross-resistance and similar toxicities within the groups. Group 4 consists of less potent oral agents: ethionamide, prothionamide, cycloserine, terizidone, and *p*-aminosalicylic acid. Group 5 is composed of drugs for which antituberculosis action has not been documented in clinical trials (except for thioacetazone): clofazimine, linezolid, amoxicillin/clavulanate, thioacetazone, imipenem/cilastatin, high-dose isoniazid, and clarithromycin. A drug that has been used within a failing regimen should never be counted in the total of four drugs for retreatment, even if susceptibility is shown in the laboratory. The doses and adverse effects of second-line drugs are described in detail in the ATS/CDC/IDSA recommendations for treatment of tuberculosis.²⁹⁹

Two new second-line drugs, delamanid and bedaquiline, have been introduced, although as of this writing only bedaquiline has been approved by the U.S. Food and Drug Administration.³⁶⁵⁻³⁶⁸ Given the paucity of data describing outcomes and adverse events, the WHO recommends that bedaquiline may be added to a WHO-recommended regimen in adult patients with pulmonary tuberculosis caused by MDR organisms. The recommendations also specify fairly rigid conditions under which the drug should be used. Thus, informed consent should be obtained from the patient and there should be careful monitoring for adverse drug effects.

Empiric treatment regimens are commonly used while the drug susceptibility results are pending. Empiric regimens are strongly recommended to avoid clinical deterioration and to prevent transmission of MDR strains of *M. tuberculosis* to contacts while awaiting the drug susceptibility results. Once the results of drug susceptibilities are known, an individualized regimen can be started. Individualized treatment regimens (based on susceptibility profiles and drug history of individual patients, or on local patterns of drug utilization) have the advantage of avoiding toxic and expensive drugs to which the MDR strain is resistant. However, an individualized approach requires access to substantial human, financial, and technical (laboratory) capacity. Drug susceptibility tests for second-line drugs are notoriously difficult to perform, largely because of drug instability and the fact that critical concentrations for defining drug resistance are close to the *minimal inhibitory concentration* (MIC) of individual drugs.³⁶⁹

A shorter-course standardized regimen used in Bangladesh has been described with good results reported in a small observational study.³⁷⁰ Although promising, at this point there is insufficient evidence to recommend the use of this regimen for treating MDR tuberculosis. A clinical trial is under way that should provide substantial new information on which to base recommendations. Current advice from WHO is that a short regimen for MDR tuberculosis should be used only under research conditions.³⁷¹

The outcomes of treatment for patients with MDR or XDR tuberculosis have been assessed in two systematic reviews. In the review by Johnson and colleagues³⁷² an estimated 62% of patients had successful outcomes, 13% defaulted, and 11% died. Factors associated with worse outcome included male gender, alcohol abuse, smear positivity at diagnosis, fluoroquinolone resistance, and an XDR resistance pattern. Factors associated with successful outcome were surgical intervention, no previous treatment,

and inclusion of a fluoroquinolone in the regimen (when the isolate is susceptible).

Orenstein and associates³⁷³ noted that studies combining both at least an 18-month treatment duration and directly observed treatment had significantly higher estimated success—69%, compared with other studies of treatment outcomes wherein the estimated success was 58%. Moreover, individualized regimens had an estimated success of 64%, compared with standardized regimens in which the estimated success was 54%, although the difference was not statistically significant.

More limited experience with treatment of XDR tuberculosis suggests a substantially worse outcome. In a meta-analysis of outcomes in 560 patients, Jacobson and colleagues³⁷⁴ reported a successful outcome in an estimated 44%. Their analysis also suggested that the use of a later-generation fluoroquinolone was associated with a better outcome. Substantial treatment support is commonly necessary to enable patients to complete a second-line regimen. MDR/XDR tuberculosis treatment is a complex health intervention: consultation with a specialist experienced in the management of these patients is strongly advised. Often second-line drugs are the last best hope for patients with drug-resistant tuberculosis, and it is crucial that such treatment be designed for maximal effectiveness with the active participation of the patient to overcome the challenges faced by both provider and patient with MDR/XDR tuberculosis.³⁷⁵

Of great concern, tuberculosis caused by organisms resistant to all drugs tested has been described in India but likely exists elsewhere as well.^{376,377} However, because of uncertainties about the connection between second-line drug susceptibility test results and patient outcomes, it is not clear that there are no treatment options. Nevertheless, at least at this time, there are no specific recommended treatment options for such patients and symptomatic or palliative care may be required. Although the number of such cases is likely to be small, providers should be attuned to the possibility of such situations and be prepared to provide appropriate palliative management to relieve suffering caused by the disease.

Treatment in Other Patient Groups

Children. The basic principles that apply in the management of adults with pulmonary tuberculosis are equally applicable in children. Although children have been excluded from nearly all clinical trials of short durations of chemotherapy, there are several reports documenting the usefulness of 6- and 9-month regimens in children.^{378,379} The most frequent difference between treating children and adults is the more limited use of ethambutol. Because children tend to have forms of tuberculosis that are associated with lower bacillary populations, the likelihood of drug resistance is less. Moreover, young children generally cannot have visual acuity testing performed accurately and thus cannot be monitored for toxicity. However, if ethambutol is used, the dose should be increased to 20 mg/kg because of differences in pharmacokinetics between adults and children.³⁸⁰ At least in younger children, sputum specimens for bacteriologic evaluations cannot usually be obtained.³⁸¹ Consequently, the response to treatment is assessed by clinical and radiographic criteria. For this same

reason, drug susceptibility or resistance often must be inferred from the pattern of the presumed source case or community data rather than being determined in the laboratory.

The management of children with drug-resistant tuberculosis is especially difficult because of the lack of culture and susceptibility testing to guide treatment. Consequently there is limited evidence to guide optimal treatment and follow-up in children. However, the basic principles and approaches described for drug-resistant tuberculosis, including MDR and XDR tuberculosis, apply in both children and adults.³⁸²

Pregnancy and Breast-feeding. Active untreated tuberculosis poses a far greater hazard to a pregnant woman and her fetus than does treatment for the disease.³⁸³ Pregnant women or mothers of young infants, therefore, should be started on treatment with isoniazid, rifampin, and ethambutol. Pyrazinamide is included in recommendations for treating tuberculosis in pregnant women by the WHO, but it has not been included in recommendations in the United States because of insufficient information about possible harm to the fetus. Streptomycin, which interferes with development of the ear and may cause congenital deafness, is the only antituberculosis drug documented to have harmful effects on the fetus.³⁸⁴ This potential is presumably shared by amikacin, kanamycin, and capreomycin; however, there is little or no information about the effects of these drugs on the fetus, or about the potential hazards of cycloserine, ethionamide, and pyrazinamide. Although several antituberculosis drugs are present in breast milk, their concentrations and the total amounts that could possibly be ingested by a nursing infant are such that adverse effects would be unlikely. Thus, no modifications of treatment regimens are recommended for nursing mothers.²⁹⁹

Associated Conditions. Tuberculosis commonly develops in association with other conditions, either because an underlying disease or its treatment alters immune responsiveness, thereby predisposing to tuberculosis (e.g., HIV infection, hematologic or reticuloendothelial malignancies, chronic renal disease or diabetes mellitus, use of tumor necrosis factor inhibitors), or because the accompanying condition is common in the same social and cultural milieu as tuberculosis, particularly alcoholism and all its complications and other forms of substance abuse.³⁸⁵⁻³⁸⁷ Because all of these conditions may affect the response to and outcome of treatment, therapeutic decisions must be made on an individualized basis and, when possible, steps must be taken to correct the immunosuppression.

In patients with impaired renal function, streptomycin, kanamycin, amikacin, and capreomycin should be avoided if at all possible or given two to three times per week in the usual dose. If there is severe impairment of renal function, reduction in frequency of administration of ethambutol and pyrazinamide to two to three times per week may be necessary.²⁹⁹ Liver disease, particularly alcoholic hepatitis and cirrhosis, is commonly associated with tuberculosis. In general, the complications of potentially hepatotoxic antituberculosis drugs have not been greater in patients with liver disease.³⁸⁸ However, detecting any such adverse effects may be difficult because of the preexisting disorder of

hepatic function. Moreover, a drug that would cause minor hepatotoxicity in a person with normal liver function could have major consequences in a patient with severe liver disease. Options in treating patients with severe liver disease include treatment without isoniazid by using rifampin, ethambutol, and pyrazinamide for 6 months; treatment without pyrazinamide for a total duration of 9 months; treatment with only one potentially hepatotoxic drug, usually retaining rifampin and adding ethambutol and a fluoroquinolone for a total of 12 to 18 months; or treatment with a regimen that contains no hepatotoxic drugs, such as streptomycin, ethambutol, a fluoroquinolone, and perhaps another second-line drug for 18 to 24 months.²⁹⁹ In patients with severe liver disease, routine testing of liver function should be performed at baseline and frequently during treatment. Finally, in patients with psychiatric disorders, close supervision of treatment with directly observed therapy of all medications is essential.

Adjunctive Therapy

Currently, the adjunctive therapies for pulmonary tuberculosis include surgery and corticosteroid treatment. Although surgery was once a mainstay of treatment for pulmonary tuberculosis, since the advent of chemotherapy, it has rarely been indicated. Artificial pneumothorax, pneumoperitoneum, phrenic nerve interruption, plombage, and thoracoplasty—procedures designed to collapse portions of the lung and close cavities—were common interventions until the 1960s but then rendered obsolete by the effectiveness of chemotherapy.³⁸⁹ Rarely, even now, patients with MDR pulmonary tuberculosis are treated with either pneumoperitoneum or thoracoplasty.

Currently, surgical resection is the most commonly performed surgical procedure and may be indicated in several situations. In patients with tuberculosis caused by MDR or XDR organisms anatomically limited within the lung and who are otherwise deemed to be surgical candidates, resection may be an effective therapeutic option. A systematic review and meta-analysis suggested that the outcomes were improved in patients who underwent surgery in addition to medical therapy.³⁹⁰ The outcome assessed at 12 months postprocedure was estimated as successful in 87% of patients who underwent surgery for MDR tuberculosis. All-cause mortality was 6%. The results for patients with XDR tuberculosis were estimated to be 69% successful with an all-cause mortality of 4%. However, the literature is difficult to interpret because of differences in case selection for surgical procedures, differences in the procedures performed (which often are not stated in meta-analyses), variations in extent of the tuberculous process, differing drug regimens, and finally the fact that controlled clinical trials have not been done (and would be difficult to design).

Ideally, before surgery the bacillary population should be reduced as much as possible with drugs to which the organism is susceptible. However, the timing of surgery can be difficult, in that the effectiveness of a limited second-line drug regimen cannot always be predicted. Resection may also be necessary because of massive hemoptysis associated with current or old tuberculosis, because of residual lung damage (e.g., bronchiectasis) exacerbated by recurrent bacterial infections, or because of a bronchopleural fistula usually with a tuberculous empyema. In addition to these

therapeutic indications for surgery, tuberculosis is sometimes diagnosed by examination of a pulmonary mass or nodule that was resected owing to suspicion of malignancy.

In any situation involving possible lung surgery in patients with or suspected of having tuberculosis, including the resection of a solitary nodule in a patient with a positive tuberculin reaction, it is desirable for the patient to have been receiving adequate antituberculosis chemotherapy before the operation. This will minimize the possibility of spread of tuberculosis within the lung and of bronchial stump infection and empyema. The optimum amount of time before operation that treatment should be given is not clear, but in emergencies, such as massive hemoptysis, at least single doses of the drugs should be given, whereas with elective procedures, it is desirable to wait at least until the sputum smear is negative. If the sputum smear is negative to begin with, 2 weeks of treatment is reasonable.

Corticosteroids. The use of corticosteroids in pulmonary tuberculosis has been and remains controversial. In view of the well-known effects of corticosteroids in decreasing cell-mediated immune responses, it seems counterintuitive that these same agents could be beneficial. Nevertheless, corticosteroids, by interfering with the tissue-damaging immune response, may minimize the adverse effects of the inflammatory reaction. For this reason, corticosteroids may under certain conditions be of benefit in patients with pulmonary tuberculosis who are receiving adequate chemotherapy. These conditions were defined by a controlled trial reported by Johnson and colleagues³⁹¹ in which all patients were treated with effective antituberculosis chemotherapy (although rifampin was not yet available) and were assigned at random to receive either methylprednisolone or placebo. This study demonstrated that corticosteroid treatment most benefited the seriously ill patient (defined by low serum albumin concentration, low body weight, and severe weight loss) who had extensive tuberculosis. This benefit was evidenced mainly by an increase in the rate of radiographic clearing; there was no adverse effect on the bacteriologic response. In less severely ill patients, methylprednisolone was either of no benefit or actually decreased the speed of sputum conversion. These data suggest that the major role of corticosteroid treatment is in patients with severe tuberculosis and severe systemic effects. Although not considered in the study by Johnson and colleagues, steroids may also be of benefit in patients with marked abnormalities of gas exchange and respiratory failure.³⁹² A more recent systematic review examined the results of clinical trials of corticosteroids as adjunctive therapy for pulmonary tuberculosis and came to essentially the same conclusions.³⁹³ Dexamethasone is also recommended in tuberculous meningitis¹⁶⁶ and, although the evidence is less persuasive, corticosteroids are often given in tuberculous pericarditis.

EXTRAPULMONARY TUBERCULOSIS

Extrapulmonary tuberculosis presents more of a diagnostic and therapeutic problem than does pulmonary tuberculosis. In part this relates to its being less common and therefore

less familiar to most clinicians.^{394,395} In addition, extrapulmonary tuberculosis involves relatively inaccessible sites, and often, because of the vulnerability of the areas involved, much greater damage can be caused by fewer bacilli. The combination of small numbers of bacilli in inaccessible sites makes bacteriologic confirmation of a diagnosis more difficult, and invasive procedures are frequently necessary to establish a diagnosis. In addition to the need for invasive diagnostic procedures, surgery may be an important component of management.

In 2012 in the United States, 21% of newly reported cases of tuberculosis involved extrapulmonary sites only and an additional 10% involved both pulmonary and extrapulmonary sites.²⁷ The proportion of patients with extrapulmonary involvement is greater among patients with HIV infection. In one large retrospective study of tuberculosis in patients with HIV infection, approximately one third of the patients had only extrapulmonary sites of involvement, one third had both pulmonary and extrapulmonary disease, and one third had only pulmonary involvement.³⁹⁶ Because of the frequency of extrapulmonary tuberculosis among HIV-infected patients, diagnostic specimens from any suspected site of disease should be cultured for mycobacteria, including blood and bone marrow from any febrile patient who does not have an obvious localized site of disease.

LYMPHATIC TUBERCULOSIS

Lymphatic tuberculosis accounts for approximately 42% of the cases of extrapulmonary tuberculosis in the United States.²⁷ Although the basic descriptive epidemiology of tuberculosis applies to lymphatic tuberculosis, there are a few differences. This form of tuberculosis is more common among children than among adults. In addition, lymphatic tuberculosis differs from the overall pattern in that it happens more frequently in women. It also appears to be more common among Asians and Pacific Islanders than among blacks and whites. Among HIV-infected persons, the incidence of tuberculous lymphadenitis increases as the level of CD4⁺ T cells decreases.³⁹⁷

Tuberculous lymphadenitis usually presents as painless swelling of one or more lymph nodes. The nodes most commonly involved are those of the posterior or anterior cervical chain or those in the supraclavicular fossa. Frequently the process is bilateral, and other noncontiguous groups of nodes can be involved. At least initially, the nodes are discrete and the overlying skin is normal. With ongoing disease, the nodes may become matted and the overlying skin inflamed. Rupture of the node can result in formation of a sinus tract, which may persist for years. Intrathoracic adenopathy may compress bronchi, causing atelectasis, thereby leading to lung infection and perhaps bronchiectasis. Although rare, upper airway obstruction may result from cervical node enlargement. Both chylous pleural effusion and ascites have resulted from intrathoracic or abdominal node involvement with obstruction of retroperitoneal lymphatics or the thoracic duct. Tuberculous lymphadenitis may also appear or worsen as a manifestation of IRIS (see Fig. 35-12).

The diagnosis of tuberculous lymphadenopathy is established by lymph node biopsy or aspiration with histologic examination, including stains for acid-fast organisms and

culture of the material. Smears show acid-fast organisms in approximately 25% to 50% of biopsy specimens, and *M. tuberculosis* is isolated in approximately 70% of instances in which the final diagnosis is considered to be tuberculosis.³⁹⁸ Caseating granulomas are seen in nearly all biopsy specimens from immunocompetent patients. In immunodeficiency states, granulomas may be poorly formed or absent.³⁹⁹

The rate of response of tuberculous lymphadenitis to the standard 6-month regimen is much slower than that of pulmonary tuberculosis. Nodes may enlarge, new nodes may appear, and fistulas may develop during treatment that ultimately proves effective, but true bacteriologic relapse after completion of therapy is unusual.⁴⁰⁰

Corticosteroid treatment has been used to shrink intrathoracic nodes and relieve bronchial obstruction, primarily in children. In a controlled study, Nemir and coworkers⁴⁰¹ demonstrated that corticosteroids increase the rate of resolution of radiographic changes thought to be due to bronchial narrowing by lymph nodes or endobronchial lesions in children with primary tuberculosis. Apart from this indication, there is no clear role for corticosteroids in lymphatic tuberculosis.

Surgical intervention may be necessary to make a diagnosis of tuberculous lymphadenitis and, on occasion, surgical incision and drainage are needed to prevent spontaneous drainage and fistula formation. Surgical excision of involved nodes, strictly as an adjunct to chemotherapy, is associated with perhaps a slightly worse outcome than medical treatment with aspiration of the node or medical treatment alone.⁴⁰²

Various other forms of extrapulmonary tuberculosis, including genitourinary, bone and joint, central nervous system, abdominal, and pericardial tuberculosis are discussed in the online version of this chapter.

TREATMENT OF LATENT TUBERCULOUS INFECTION

The observations on which treatment of LTBI are based were made in the 1950s. In these experimental studies, it was found that animals given isoniazid before being challenged by *M. tuberculosis* had a much lower frequency of tuberculosis.⁴³¹ Subsequently, it was found that isoniazid given to children with primary tuberculosis nearly eliminated extrapulmonary spread of the disease.⁴³² These results provided the rationale for several large U.S. Public Health Service studies of the effectiveness of isoniazid in preventing tuberculosis. These studies were double-blind, placebo-controlled clinical trials that involved approximately 70,000 participants who were in a number of different settings and who had a variety of different risk factors for tuberculosis. The design and results of these studies are described in detail by Ferebee.⁴³³ The findings were remarkably similar in all groups studied; participants given isoniazid had a reduction of approximately 80% in the incidence of tuberculosis during the year the medication was given, in comparison with those given placebo. The protective effect decreased during subsequent years, but the treated groups still showed approximately 50% less

tuberculosis than did the control groups each year after the medication year through 10 to 12 years of observation. Overall, isoniazid reduced the incidence of tuberculosis by approximately 60%.

The effectiveness of antituberculosis drugs in preventing tuberculosis is presumably a result of the reduction of the viable population of sequestered bacilli in inactive or radiographically invisible lesions in the lungs and elsewhere. However, on occasion, treatment may be given to persons who have been exposed to tuberculosis but do not have a positive TST or IGRA. In this situation, treatment is assumed to prevent the establishment of a tuberculous infection, an example of “primary prophylaxis.” However, the effectiveness of antituberculous drugs in preventing tuberculosis is limited in high-prevalence populations: a recent large trial in South African gold miners found only a temporary benefit of isoniazid preventive treatment, most likely because of frequent re-exposure to tuberculosis after the end of the treatment.^{433a}

INDICATIONS FOR TREATMENT

The recommendations for testing for and treatment of LTBI reflect the concept that only persons who are at increased risk of tuberculosis should be tested for latent infection; thus, any person who is tested and is found to have a positive test should be considered for treatment.^{434,435} The two broad categories of persons in whom the risk of tuberculosis is substantially higher than that of the general population of the United States are persons who are either known or presumed to have been recently infected with *M. tuberculosis* and persons who have clinical conditions that increase the risk of progressing from latent infection to active tuberculosis. The specific groups in which treatment is indicated are as follows (in order of decreasing degree of risk for developing tuberculosis).

Persons with HIV Infection

A number of studies have shown that the rates of tuberculosis among persons who are infected with both *M. tuberculosis* and HIV are extremely high, ranging from 3% to 10% per year.^{436,437} The effectiveness of preventive therapy among persons with HIV infection has been examined in a Cochrane review that included data through April 2008.⁴³⁸ Preventive therapy (with any anti-TB drug) versus placebo was associated with a lower incidence of active tuberculosis with a *relative risk* (RR) of 0.68. The benefit was greater in individuals with a positive TST (RR 0.38) than in those who had a negative test (RR 0.89). The efficacy was similar for all regimens, regardless of drug type, frequency, or duration of treatment. However, compared with isoniazid monotherapy, short-course multidrug regimens were much more likely to require discontinuation of treatment due to adverse effects. Although there was reduction in mortality with isoniazid monotherapy, there was no evidence that preventive therapy reduced all-cause mortality.

Currently WHO recommends isoniazid given for at least 6 months to persons with HIV infection at risk of tuberculosis regardless of the TST result. Some data suggest that a 36-month treatment duration further reduces the risk of tuberculosis in persons with HIV infection in a high tuber-

culosis incidence country, perhaps by reducing reinfection with *M. tuberculosis*.⁴³⁹ However, this regimen is not recommended by WHO at this time.

Likewise, although there are data showing efficacy of the 12-dose isoniazid-rifapentine regimen in adults with HIV infection, it is not yet recommended by WHO.⁴⁴⁰ Although antiretroviral therapy has a substantial effect in reducing the risk of tuberculosis, there is additive benefit from isoniazid preventive treatment.^{197,199,441}

Close Contacts of New Cases

Two percent to 4% of persons in close contact with a person with infectious tuberculosis develop tuberculosis in the year after exposure.⁴⁴²⁻⁴⁴⁴ In young children and adolescents, the risk is perhaps twice that in adults. Because the TST or IGRA result may be negative if infection is recent, all close contacts should be treated. Those with a TST of 5 mm or more should be considered to be infected and should receive a full course of preventive therapy. Close contacts who have negative TST should be retested 2 to 3 months after the index case has ceased being infectious or after contact has been broken. If the TST at that time is less than 5 mm or if the IGRA has not converted, isoniazid can be discontinued; if the reaction is 5 mm or more or an IGRA has converted from negative or indeterminate to positive, the drug should be continued for a full course. Contacts known to be HIV-infected should be treated even if the TST result is negative.⁴³⁴

Persons with Recent Infection

As discussed in the section describing the pathogenesis of tuberculosis, the risk of developing tuberculosis is greatest during the initial 1 to 2 years after acquisition of the infection. Any person who is documented to have had a conversion of the TST or an IGRA from negative to positive should be considered newly infected and receive treatment. A skin test conversion is defined as an increase in reaction size of 10 mm or more within a 2-year period for persons younger than 35 and a 15-mm or more increase for persons older than 35. TST reactors younger than 5 years of age should be accorded a high priority for preventive therapy, both because they obviously have been infected relatively recently and because of the potential for severe disease in this age group. There is no consensus on the change in the IGRA result to define a conversion.

Persons with Stable Radiographic Findings Consistent with Previous Tuberculosis

This group includes persons with a history of tuberculosis who never received chemotherapy or were not treated adequately and persons with no known history of the disease. The rate at which new episodes of tuberculosis develop in these groups ranges from approximately 0.4% to 3.5% per year.⁴⁴⁵⁻⁴⁴⁷ The risk is lowest in persons with small lesions that have been stable for a long period. In persons with radiographic abnormalities, it is essential that current tuberculosis be excluded by a careful clinical and bacteriologic evaluation. Because exclusion of active tuberculosis might not be feasible or possible at the initiation of therapy, an alternative approach is to begin therapy with multiple drugs: isoniazid, rifampin, and pyrazinamide, sometimes with ethambutol. If disease is determined to be active by a

GENITOURINARY TUBERCULOSIS

The epidemiologic pattern of genitourinary tuberculosis parallels that of tuberculosis in general, with the exception of HIV-infected patients. The pathogenesis is thought to be due to seeding of the kidney at the time of the initial infection and bacilleemia. This mechanism is supported by the finding that, with careful study, tuberculous lesions can be found in both kidneys in 90% of patients with renal tuberculosis, even though the disease is clinically evident in only one kidney.⁴⁰³ Lower genitourinary tract involvement is thought to represent spread from the kidneys, but it may also represent spread by hematogenous seeding. Genital lesions were reported by Medlar and coworkers⁴⁰⁴ in 13% of men with disseminated renal lesions, 52% of those with caseating lesions, and 100% of those with cavitary lesions in the kidney. Genital involvement without renal involvement was reported in 11%.

In patients with genitourinary tuberculosis, local symptoms predominate and systemic symptoms are less common.^{405,406} Dysuria, hematuria, and frequent urination are common, and flank pain may also be noted. However, in general the symptoms are subtle, and often there is advanced destruction of the kidneys by the time a diagnosis is established.⁴⁰⁷ In women, genital involvement is more common without renal tuberculosis than in men and may cause pelvic pain, menstrual irregularities, and infertility as presenting complaints.⁴⁰⁶ In men, a painless or only slightly painful scrotal mass is probably the most common presenting symptom of genital involvement, but symptoms of prostatitis, orchitis, or epididymitis may also exist.⁴⁰⁵ A substantial number of patients with any form of genitourinary tuberculosis are asymptomatic, and the disease is detected because of an evaluation for an abnormal urinalysis. In patients with renal or genital tuberculosis, urinalyses are abnormal in more than 90%; the main findings are pyuria, hematuria, or mixed pyuria and hematuria. Pyuria in an acidic urine with no organisms isolated from a routine urine culture should prompt an evaluation for tuberculosis. Occasionally, when there is an isolated genital focus of disease or when a tuberculous kidney is blocked by a ureteral stricture, the urinalysis may be normal and cultures may be sterile.

The suspicion of genitourinary tuberculosis should be heightened by the presence of abnormalities on the chest film. In most series, 50% to 75% of patients have chest radiographic abnormalities, although many of these may be the result of previous, not current, tuberculosis.^{405,406}

When genitourinary tuberculosis is suspected, at least three first-voided early morning urine specimens should be collected and stained for AFB and cultured for mycobacteria. In men, saprophytic *Mycobacterium smegmatis* may cause a positive smear. However, in the presence of abnormalities suggesting tuberculosis, the finding of a positive smear should be interpreted as confirming the diagnosis of genitourinary tuberculosis until the results of cultures are known. *M. tuberculosis* is isolated from the urine in 80% to 95% of cases of genitourinary tuberculosis.^{405,406} Diagnosis of isolated genital lesions usually requires biopsy because the differential diagnosis often includes neoplasia, as well as other infectious processes.

Positive urine cultures may manifest in the absence of any clinical, laboratory, or radiographic findings, which suggests concomitant genitourinary tuberculosis in patients with other forms of tuberculosis. Bentz and coworkers⁴⁰⁸ found unanticipated positive urine cultures in 21% of patients with other extrapulmonary forms of tuberculosis and in 5% of those with pulmonary tuberculosis alone.

Renal tuberculosis, at least as indicated by a positive urine culture, may develop in patients with HIV infection. In one series, positive urine cultures were found in 12 (71%) of 17 cultures submitted in patients with tuberculosis and advanced HIV infection, although this was not a systematic sampling.³⁹⁶

There are several treatment considerations for genitourinary tuberculosis apart from standard chemotherapy. Nephrectomy, formerly a mainstay of therapy for renal tuberculosis, now is seldom indicated; however, in patients who have tuberculosis caused by MDR organisms and who can tolerate removal of a kidney, nephrectomy may be indicated. Nephrectomy may also be indicated for patients who have recurrent pyogenic bacterial infections in a kidney destroyed by tuberculosis, for patients with persistent pain, and for those with massive hematuria. Surgical or endoscopic procedures may also be necessary to correct ureteral strictures and to augment the capacity of a contracted bladder.

BONE AND JOINT TUBERCULOSIS

The incidence of tuberculosis involving the joints and bones increases with increasing age and is equally frequent among men and women. In comparison with blacks and whites, other racial groups are less likely to have skeletal involvement. Skeletal tuberculosis does not appear to be more frequent in persons with HIV infection.

It is presumed that most osteoarticular tuberculosis results from endogenous reactivation of foci of infection seeded during the initial bacilleemia, although spread from paravertebral lymph nodes has been postulated to account for the common localization of spinal tuberculosis to the lower thoracic and upper lumbar vertebrae. It is also postulated that the predilection for tuberculosis to localize in the metaphyses of long bones is due to the relatively rich blood supply and scarcity of phagocytic cells in this portion of the bone.⁴⁰⁹ After beginning in the subchondral region of the bone, the infection spreads to involve the cartilage, synovium, and joint space. This produces the typical findings of metaphyseal erosion and cysts and loss of cartilage with narrowing of the joint space. Typically, in the spine these changes involve two adjacent vertebrae and the intervertebral disc (eFig. 35-1). An "atypical" form of spondylitis without evidence of disc involvement may be seen and may account for more than half of the patients.⁴¹⁰⁻⁴¹² Paravertebral or other para-articular abscesses may develop with occasional formation of sinus tracts. Although weight-bearing joints are the most common sites for skeletal tuberculosis, any bone or joint may be involved.⁴⁰⁹ In most series of osteoarticular tuberculosis, tuberculosis of the spine (Pott disease) makes up 50% to 70% of the cases reported. In adults the lower thoracic and upper lumbar vertebrae are most commonly involved, whereas in children the upper

thoracic spine is the most frequent site. The hip or knee is involved in 15% to 20% of cases, and shoulders, elbows, ankles, wrists, and other bones or joints also make up 15% to 20%. Usually only one bone or joint is involved, but occasionally the process may be multifocal. Evidence of either previous or current pulmonary tuberculosis is found in approximately half the reported patients, and other extrapulmonary sites may be involved as well.

The first diagnostic test undertaken is usually a radiograph of the involved area. Early in the process, the only abnormality noted may be soft-tissue swelling. *Computed tomography* (CT) scans and magnetic resonance imaging of the spine are considerably more sensitive than routine films and should be obtained when there is a high index of suspicion of an infectious process. Radionuclide bone scanning with technetium-99m can demonstrate occult skeletal involvement in patients with normal radiographs. Likewise, gallium-67 scanning may define unsuspected sites, especially soft-tissue involvement not seen on the bone scan.

Confirmation of the diagnosis is obtained by aspiration of joint fluid or periarticular abscesses or by biopsy of bone or synovium with histologic and microbiologic evaluation of the material obtained. Acid-fast stains are positive in 20% to 25% of samples of joint fluid, and *M. tuberculosis* is isolated in approximately 60% to 80% of them.⁴⁰⁹ Biopsy specimens of synovium or bone have a higher yield and enable histologic examination as well. Evidence of granulomatous inflammation even in the absence of bacteriologic proof of the diagnosis is sufficient evidence of tuberculosis to begin therapy unless another cause is found.

Standard chemotherapy of 6 to 9 months' duration is highly successful in skeletal tuberculosis, but surgery is occasionally a necessary adjunct.⁴¹⁰ The longer duration of treatment has been suggested because of the difficulties in assessing response. Several controlled studies have documented that chemotherapy conducted largely on an ambulatory basis is effective in curing spinal tuberculosis without the need for immobilization.⁴¹¹ The role of emergency spinal cord decompression in patients with Pott disease and early neurologic findings is not clear, and, if paraplegia is already present, the benefit of surgical intervention is even less clear. Moreover, there is no well-defined surgical procedure of choice. An "all-or-none" approach has been advocated by several surgeons,⁴¹²⁻⁴¹⁴ which means that surgery is not performed except in patients with progressive neurologic deterioration unresponsive to chemotherapy—in whom all affected bone is removed and an anterior spinal fusion is performed; there is no role for simple debridement other than for diagnosis. Surgery may be indicated in other forms of articular tuberculosis when there is extensive destruction of the joint or surrounding soft tissues, in which case synovectomy and joint fusions may be necessary.

CENTRAL NERVOUS SYSTEM TUBERCULOSIS

Meningitis is the most frequent form of central nervous system tuberculosis; solitary or multiple tuberculomas ensue less commonly. The epidemiologic pattern of central nervous system tuberculosis is quite different from that of either pulmonary or other forms of extrapulmonary tuberculosis, in that the peak incidence is in infants and children up to age 4. Although an appreciable number of cases exist

in adults, meningitis accounts for only approximately 6% of all cases of extrapulmonary tuberculosis, which are equally divided between males and females.²⁷

Central nervous system tuberculosis, especially tuberculomas, seems to develop with greater frequency among HIV-infected persons. Central nervous system tuberculomas have been reported even in patients who are receiving what should be adequate chemotherapy.⁴¹⁵ Because tuberculomas may be indistinguishable on CT scan from the lesions of toxoplasmosis, specific diagnosis is necessary.

Meningitis presumably can result from direct meningeal seeding and proliferation during a tuberculous bacilleemia either at the time of initial infection or reactivation of an old pulmonary focus, or it can also result from reactivation of an old parameningeal focus with rupture into the subarachnoid space.⁴¹⁶ The consequences of the subarachnoid space contamination include diffuse meningitis, a localized arteritis, encephalitis, and myelitis. The symptoms depend primarily on which of these processes predominates. With meningitis, the process is primarily located at the base of the brain.⁴¹⁷ Symptoms therefore include those related to cranial nerve involvement in addition to headache, decreased level of consciousness, and neck stiffness. The duration of illness before diagnosis is variable and related partly to the presence or absence of other sites of involvement. In a large series of patients, the average duration of illness was 12 days.⁴¹⁸ In most series, more than 50% of patients with meningitis have abnormalities on chest film that are consistent with an old or current tuberculous process, often miliary tuberculosis. At autopsy, disseminated disease is found in a high percentage of patients with meningitis. In patients with tuberculous meningitis, sputum cultures have been positive in 40% to 50%; thus, a substantial number of patients have pulmonary and systemic symptoms in addition to those referable to the central nervous system. Patients in whom arteritis is the predominant manifestation of meningitis can present with a variety of focal central nervous system ischemic syndromes in addition to the symptoms already described.

In tuberculous meningitis, the lumbar puncture usually shows increased opening pressure, and the *cerebrospinal fluid* (CSF) usually contains between 100 and 1000 cells/ μ L.^{394,418} In approximately 65% to 75% of patients, lymphocytes predominate, whereas polymorphonuclear leukocytes predominate in the remainder, generally early in the course of the illness. The CSF protein concentration is elevated in nearly all patients. Very high (>3300 mg/dL) protein concentrations have been associated with a poor prognosis; the glucose concentration in CSF is usually low, but not as low as that often found in pyogenic bacterial meningitis.⁴¹⁸ Acid-fast organisms are seen on smears of CSF in only 10% to 20% of patients, and the rate of culture positivity varies from 25% to 80% but is generally in the lower end of the range.⁴¹⁸ In a substantial number of patients, *M. tuberculosis* is isolated from other sources, which, in the presence of compatible CSF findings, is sufficient to diagnose tuberculous meningitis. In view of the severity of tuberculous meningitis, a presumptive diagnosis justifies empirical treatment if no other diagnosis can be established promptly. Because of the difficulty with establishing a diagnosis of tuberculous meningitis by bacteriologic methods, Thwaites and associates⁴¹⁸ developed and

validated a clinical scoring system by which tuberculous meningitis could be separated from pyogenic bacterial meningitis. Younger age (<36 years), lower peripheral white blood cell count (<15,000/mm³), longer duration of illness (>6 days), lower CSF white blood cell count (<900/μL), and lower percentage (<75%) of neutrophils in the CSF were associated with a greater likelihood of a tuberculous etiology.

A meta-analysis of 14 studies of nucleic acid amplification tests for the diagnosis of tuberculous meningitis found a combined sensitivity of 56% and a specificity of 98%.³⁰⁹ Thus, when a nucleic acid amplification test is positive, one can assume that the etiology is tuberculous, but a negative result does not exclude the diagnosis.

If there are no epidemiologic indicators of possible resistance, a treatment regimen of isoniazid, rifampin, pyrazinamide, and ethambutol should be effective. The recommended length of the continuation phase is at least 7 months, for a total treatment duration of 9 to 12 months, although there are no clinical trials that serve to define the optimum treatment duration.

Corticosteroid treatment has a beneficial effect in patients with tuberculous meningitis and cerebral edema,³¹⁵ and it decreases the frequency of adverse sequelae in children with less advanced disease.⁴¹⁹ Given the poor prognosis of tuberculous meningitis, the reasonably good data supporting corticosteroid use in more severe forms of the disease, and the paucity of information in patients with less advanced disease, corticosteroid treatment, specifically with dexamethasone, is recommended for all patients³¹⁵ at a dosage of 12–16 mg/day for 3 weeks, then decreased gradually during the next 3 weeks. Even with effective chemotherapy and corticosteroids, however, both the mortality rate and rate of residual neurologic abnormalities from tuberculous meningitis remain high.

The other major central nervous system form of tuberculosis, the tuberculoma, presents a more subtle clinical picture than does tuberculous meningitis.⁴²⁰ The usual presentation is that of a slowly growing focal lesion, although a few patients have increased intracranial pressure and no focal findings. The CSF is usually normal, and the diagnosis is established by CT scanning or magnetic resonance imaging and subsequent resection, biopsy, or aspiration of any ring-enhancing lesion. The response to antituberculous chemotherapy is good, and corticosteroids are indicated only if there is an increase in intracranial pressure.

ABDOMINAL TUBERCULOSIS

Tuberculosis can involve any intra-abdominal organ and peritoneum. The age distribution of abdominal tuberculosis shows a higher incidence in young adults and a second peak in older persons. Men and women have similar incidences. The abdomen is a common site of disease in HIV-infected persons.

Abdominal tuberculosis presumably results from seeding at the time of initial infection and then either direct or late progression to clinical disease. Peritonitis can also be caused by rupture of tuberculous lymph nodes within the abdomen, and intestinal tuberculosis may result from direct implantation in the gut of ingested tubercle bacilli. Before the advent of chemotherapy, tuberculous enteritis was common in

patients with advanced pulmonary tuberculosis, presumably being caused by swallowed bacilli from the lungs. In a prospective study conducted between 1924 and 1949, intestinal abnormalities compatible with tuberculous enteritis were found by contrast radiography in 1%, 4.5%, and 24.7% of patients with minimal, moderately advanced, and far advanced pulmonary tuberculosis, respectively.⁴²¹

The clinical manifestations of abdominal tuberculosis depend on the areas of involvement. In the gut itself, tuberculosis may be in any location from the mouth to the anus, although lesions proximal to the terminal ileum are unusual. The most common sites of involvement are the terminal ileum and cecum; other portions of the colon and the rectum are involved less frequently.⁴²² In the terminal ileum or cecum, the most common manifestations are pain (which may lead to a misdiagnosis of appendicitis) and intestinal obstruction. A palpable mass may be noted that, together with its radiographic appearance, can easily be mistaken as a carcinoma. Rectal lesions usually present as anal fissures or fistulas or perirectal abscesses. In addition to carcinoma, the differential diagnosis of these findings includes inflammatory bowel disease. Because of the concern regarding carcinoma, the diagnosis often is made through surgery.⁴²³

Tuberculous peritonitis commonly causes pain as its presenting manifestation, often accompanied by abdominal swelling. Fever, weight loss, and anorexia are also common. Active pulmonary tuberculosis is uncommon in patients with tuberculous peritonitis. Because the process frequently coexists with other disorders, especially cirrhosis with ascites, the symptoms of tuberculosis may be obscured. The combination of fever and abdominal tenderness in a person with ascites should always prompt an evaluation for intra-abdominal infection, and paracentesis should be performed. Ascitic fluid in tuberculous peritonitis is exudative and contains between 50 and 10,000 leukocytes per microliter, the majority of which are lymphocytes, although polymorphonuclear leukocytes occasionally predominate.⁴²⁴ Acid-fast organisms are rarely seen on smears of the fluid, and cultures are positive in only approximately 50%, although the yield increases if a large volume of fluid is submitted for culture. Because of the generally low yield from culture of the fluid, laparoscopic biopsy is often necessary to confirm the diagnosis.

Standard chemotherapy is effective in abdominal tuberculosis. Corticosteroids have been advocated in tuberculous peritonitis to reduce the risk of adhesions causing intestinal obstructions, but this recommendation is controversial because of the low frequency of obstruction. As discussed previously, surgery is often necessary to establish a diagnosis and, in addition, may be necessary to relieve intestinal obstruction.

PERICARDIAL TUBERCULOSIS

The descriptive epidemiology of pericardial tuberculosis is not well defined, but in general it tends to afflict older persons, particularly nonwhites and men. The pericardium may become involved during the initial bacillema, with early progression to clinically evident disease or recrudescence after a quiescent period. Hematogenous seeding may also be present during the course of endogenous

reactivation. Alternatively, there may be direct extension of an adjacent focus of disease from the lung parenchyma, pleura, or tracheobronchial lymph nodes into the pericardium. Like the pleura, the pericardium is a serosal surface capable of exuding large amounts of fluid in response to inflammation. As presumably happens in tuberculous pleuritis with effusion, it is likely that hypersensitivity plays a role in producing the intense inflammatory response and abundant effusion in the pericardium. This would account for the relative infrequency of isolation of tubercle bacilli from pericardial fluid, the nonpurulent nature of the fluid, and the generally prompt response to antituberculosis chemotherapy in most instances. Conversely, rupture of a caseous lymph node into the pericardium may cause contamination with a much greater number of organisms; a greater inflammatory response with thicker, more purulent fluid; and a greater likelihood of either early or late hemodynamic effects.

The most common form or stage of tuberculous pericarditis is characterized by pericardial effusion with little pericardial thickening or epicardial involvement. Because in most instances the fluid accumulates slowly, the pericardium can expand to accommodate large volumes (2 to 4 L) with little apparent hemodynamic compromise. Symptoms of cardiopulmonary origin tend to manifest later and include cough, dyspnea, orthopnea, ankle swelling, and chest pain. The chest pain may occasionally mimic angina but usually is described as being dull, aching, and often affected by position and inspiration.

The fluid itself is usually serosanguineous or occasionally grossly bloody, is exudative, and has a white blood cell count ranging from 500 to 50,000 cells/ μ L, with an average of 5000 to 7000 cells/ μ L.⁴²⁵ The cells are predominantly mononuclear, although polymorphonuclear leukocytes occasionally predominate. Tubercle bacilli have been identified in pericardial fluid in approximately 25% to 30% of cases (smear and culture combined).⁴²⁵ Biopsy of the pericardium with both histologic and bacteriologic evaluation is much more likely to provide a diagnosis, although a non-specific histologic pattern and failure to recover the organisms do not exclude a tuberculous cause.

Although not well documented, it appears that, if the patient survives the subacute phase without treatment, chronic fibrotic pericarditis nearly always follows. Before the advent of antituberculosis therapy, 88% of one series of patients who had tuberculous pericarditis developed evidence of chronic constriction.⁴²⁶ Constriction has also been observed to develop during the course of antituberculosis chemotherapy, although this appears to be uncommon in patients who have had symptoms for less than 3 months; it is frequent in patients who have had symptoms for more than 6 months.

The fibrotic reaction progresses to complete fusion of visceral and parietal pericardium and encasement of the heart in a rigid scar that often becomes calcified. Impairment of coronary circulation is common. At this point the histologic pattern is usually nonspecific; thus, confirmation of a tuberculous etiology is infrequent.

The definitive diagnosis of tuberculous pericarditis requires identification of tubercle bacilli in pericardial fluid or tissue. Although not conclusive, demonstration of caseating granulomata in the pericardium and consistent clinical circumstances provide convincing evidence of a tuberculous etiology. Less conclusive but still persuasive evidence is the finding of another form of tuberculosis in a patient with pericarditis of undetermined cause. Approximately 25% to 50% of patients with tuberculous pericarditis have evidence of other organ involvement, particularly pleuritis, at the time pericarditis is diagnosed.⁴²⁷ Still less direct and more circumstantial evidence of a tuberculous etiology is the combination of a positive intermediate-strength TST or IGRA reaction and pericarditis of unproved cause.

Because of the potentially life-threatening nature of pericardial tuberculosis, treatment with antituberculosis agents should be instituted promptly once the diagnosis is made or strongly suspected. It appears that the likelihood of constriction is greater in patients who have had symptoms longer; thus, early therapy may reduce the incidence of this complication. Several studies have suggested that corticosteroids have a beneficial effect in treating both tuberculous pericarditis with effusion and constrictive pericarditis.⁴²⁸⁻⁴³⁰ However, a meta-analysis of studies examining the effects of corticosteroids in tuberculous pericarditis concluded that, although steroids could have an important effect, the studies were too small to be conclusive.⁴²⁸ Nevertheless, patients with proven tuberculous pericarditis who are receiving adequate antituberculosis therapy and who have no major contraindications should receive corticosteroids. The optimum regimen is not known, but daily prednisone, 60 mg/day for 4 weeks, followed by 30 mg/day for 4 weeks, 15 mg/day for 2 weeks, and 5 mg/day for 1 week, is the recommended regimen.²⁹⁹ Corticosteroid therapy should not be used if there is a strong suspicion that the infection is caused by a drug-resistant organism unless adequate antituberculosis chemotherapy can be ensured.

In the setting of hemodynamic compromise, pericardiectomy is necessary. Although pericardiocentesis generally improves the circulatory status, the improvement is usually temporary. Pericardial windows with drainage into the left pleural space also generally provide only temporary relief. The criteria for selecting patients for pericardiectomy are not clear, apart from those patients who have refractory hemodynamic compromise.

positive culture or by radiographic improvement, therapy should be continued for 6 months. If there is no suggestion of active disease, therapy can be stopped after 4 months and the course of treatment will be sufficient for preventive purposes.⁴³⁴

Persons with Other Conditions That Increase the Risk of Tuberculosis

Although the risk of tuberculosis is not always quantifiable, there is sufficient evidence to warrant preventive therapy in certain situations: prolonged therapy with corticosteroids (usually 15 to 20 mg or more of prednisone daily, or its equivalent, for more than 2 to 3 weeks); immunosuppressive therapy; hematologic or reticuloendothelial malignancies, and perhaps certain solid tumors; end-stage renal disease; clinical conditions associated with rapid weight loss (including intestinal bypass for obesity and inadequate nutritional intake); after gastrectomy; and before treatment with anti-TNF agents; silicosis or coal workers' pneumoconiosis.^{434,448} In addition, even in the absence of any of these risk factors, persons in the following circumstances who have TST readings of 10 mm or more should be considered for preventive therapy: foreign-born persons from areas of high tuberculosis prevalence; medically underserved, low-income populations, including high-risk racial and ethnic groups; residents of long-term care facilities (e.g., correctional institutions and nursing homes); and other groups that, on the basis of local epidemiologic patterns, have been shown to have a high incidence of tuberculosis (e.g., migrant workers, homeless persons).⁴³⁴

CURRENT TREATMENT REGIMENS

For many years, the only regimen available for treating latent infection was isoniazid given for 6, 9, or 12 months. Subsequently, rifampin alone given for 4 months was shown to be effective.⁴³⁴ More recently a once-weekly combination of isoniazid and rifapentine given under direct observation for 12 doses was demonstrated to be noninferior to isoniazid alone given for 9 months.⁴⁴⁹ The CDC subsequently has published recommendations for the use of the 12-dose regimen, indicating that it should be used under direct observation in adults without HIV infection.⁴⁵⁰ The regimen that is supported most strongly is isoniazid given daily for 9 months. A 6-month regimen has also been shown to produce considerable protection and may provide the best balance between cost and benefit. Both the 6-month and the 9-month isoniazid regimens may be given twice weekly under direct observation. The second option is rifampin given daily for 4 months, although the supporting data are less strong.

Isoniazid is given in a single daily dose of 300 mg for adults and 5 to 10 mg/kg body weight (up to 300 mg/day) for children. The drug may also be given in doses of 15 mg/kg twice a week, which may facilitate direct observation of treatment. The minimum duration of treatment is 6 months; 9 months of treatment is considered optimum. Rifampin is given in a single dose of approximately 10 mg/kg body weight for both adults and children, up to a total daily dose of 600 mg. The same dose is used when the drug is given twice weekly. If rifabutin is substituted for rifampin, the dose is 5 mg/kg/day or 300 mg/day.

Treatment of LTBI with isoniazid or rifampin should not be undertaken in persons who have active, unstable liver disease. Stable chronic liver disease is not a contraindication, but such patients deserve careful consideration regarding the indications and need close attention during the course of treatment. Other persons who should be monitored especially closely during the administration of preventive therapy include persons older than 35; those taking other medications with which there may be interactions (such as phenytoin, disulfiram, or antiretroviral drugs); and persons with other disorders such as alcoholism, diabetes mellitus, or renal insufficiency that may increase the risk of adverse reactions, mainly hepatitis and peripheral neuropathy.

Pregnancy is not a contraindication to isoniazid; however, in view of the concern with elective administration of any drug during the course of pregnancy, it is generally prudent to wait until after delivery to give isoniazid. The exceptions to this general approach are women who have a documented TST conversion during pregnancy or who are HIV infected and have a positive TST.

MANAGEMENT OF EXPOSURE TO DRUG-RESISTANT ORGANISMS

Contacts of persons with drug resistant tuberculosis have a substantial risk of being infected and having active tuberculosis.⁴⁵¹ Providing preventive therapy for persons exposed to MDR or XDR organisms is especially problematic because there are no regimens with proven efficacy. The options that are available include observation only or administration of two drugs to which the source case isolate was shown to be susceptible (e.g., a 6-month regimen of ethambutol and pyrazinamide or of pyrazinamide and a fluoroquinolone). It should be noted that there are no data to guide the choice of an option. In such situations expert consultation should be obtained. Regardless of the approach that is chosen, if evidence suggesting tuberculosis arises, the patient should be treated promptly with a multidrug regimen to which the organism would be predicted to be susceptible on the basis of the susceptibility testing of the index case isolate.

IMMUNIZATION WITH BACILLE CALMETTE-GUÉRIN

Administration of BCG vaccine has been the major preventive technique used for many years throughout much of the world, yet no vaccine has been the subject of greater controversy.⁴⁵² BCG is an attenuated tubercle bacillus (*Mycobacterium bovis*) that was created beginning in 1908 by Calmette and Guérin in France and that was found to protect a variety of animal species against tuberculosis. It was first used in humans in 1921 and has since become the most widely used vaccine in the world: up to 80% of infants in developing countries receive BCG immunizations. In children, BCG has been demonstrated to prevent disseminated and miliary tuberculosis and tuberculosis meningitis.⁴⁵³ In adults, the results of BCG vaccination are less clear; of eight controlled clinical trials of BCG against pulmonary tuberculosis in adults, protection has ranged from 0 to 70%.⁴⁵²

Interestingly, when two different vaccines were used in a Medical Research Council Trial in the United Kingdom, one of which produced only poor TST reactivity, equal degrees of protection were seen. Conversely, no protection was seen in the South Indian Trial of more than 200,000 people monitored for 15 years, although all patients who developed tuberculosis had been converted to TST positivity by the vaccine.⁴⁵⁴ It is unclear why BCG appears to be effective in some parts of the world and not in others (a finding that is also evident in protection against leprosy). Clearly, there is a great deal yet to learn about the nature of protective host immune responses, host genetic factors, variations in pathogenicity of tubercle bacilli, and the role of exposure to environmental nontuberculous mycobacteria that may provide resistance or enhance susceptibility.

There are many variables that potentially could account for the discordant results. These include variations in potency of the strains of BCG used, technique of administration, handling of the vaccine, and prevalence of infection with nontuberculous mycobacteria, which may in themselves confer some degree of protection.⁴⁵⁵ Partly because of these factors, it is now generally accepted that BCG is not a tool that can be used to decrease the overall incidence of tuberculosis in a population. However, it appears that BCG reduces the likelihood of the more severe forms of the disease in children, and it is with this goal in mind that it continues to be a component of WHO immunization recommendations for developing countries. Due to the widespread acceptance and use of BCG and its benefits to young children, it is not likely that new vaccines for tuberculosis will immediately replace BCG. Instead, they will likely be used initially to boost responses after an initial dose of BCG, in an effort to induce responses that reliably protect adults against pulmonary tuberculosis.

In the United States, BCG has limited applicability. It is recommended only for TST-negative persons who are repeatedly exposed to potentially infectious patients who are being ineffectively treated. In general, the recommendation is limited to children. As a live vaccine, BCG should not be given to immunocompromised persons, including those with symptomatic HIV infection, or to pregnant women.

TACKLING CURRENT PROBLEMS

Tuberculosis is becoming a more complicated disease globally because of the appearance of MDR and XDR organisms and the increasing frequency of comorbidities, particularly HIV infection but also other risk-enhancing factors such as diabetes, renal insufficiency, immunosuppressive drugs, and tobacco and other substance addiction. Clearly, new diagnostic tools and therapeutic options are urgently needed. Currently, the most extensively used diagnostic methods around the world, both for active tuberculosis (sputum smear microscopy) and for latent tuberculosis (TST), were invented at the end of the 19th century. Similarly, BCG vaccine, despite its wide use, does not provide the needed protection. Today's standard treatment with four drugs (isoniazid, rifampin, ethambutol, and pyrazinamide) has remained unchanged for more than 30 years, must be taken for a minimum of 6 months, and is insufficient to treat patients with MDR or XDR tuberculosis. Although

there are new diagnostic methods, all of them are either an improvement of the old techniques or based on the detection of nucleic acids; none fulfill the urgent need for point-of-care diagnostic tests.

New drugs and mechanisms to reduce resistance to new drugs are a vital need, as underscored by the increase of drug-resistant tuberculosis and the detection of XDR cases.⁴⁵⁶ Also high on the list of needs is a test for the rapid detection of drug resistance suitable for point-of-care use. The current technology has identified drug targets and enabled testing of new compounds with high-throughput screening methods. Several drugs for active tuberculosis are now being tested in clinical trials.^{456,457} Some of them are candidates for first-line drugs that can reduce the treatment time, while other drugs have fewer drug interactions, with the potential benefit of being used with antiretroviral drugs. Other drugs have novel targets. However, we are still far from having a truly short treatment (currently the term *short course* is used for the 6-month regimen).

Effective vaccines will require a better understanding of the protective immune response to *M. tuberculosis* and of the pathogenesis of the disease. The availability of whole genomic sequences of thousands of clinical isolates of *M. tuberculosis*, and the recent evidence of the importance of the coevolution of the host and organism⁴⁵⁸ should assist the design of different vaccination approaches.⁴⁵⁹ A recent clinical trial demonstrated that a novel tuberculosis vaccine termed MVA85A induced the expected immune responses but failed to protect against tuberculosis when used to boost BCG vaccine in infants^{458a}; such results again demonstrate that improved understanding of tuberculosis pathogenesis and protective immunity are needed to inform development of efficacious vaccines. We are still far from understanding why the natural immune system (which prevents 90% of persons infected from developing active tuberculosis) fails in 10% of those infected and why the adaptive immune response in tuberculosis does not protect us from repeated infections. In spite of these gaps in knowledge, several additional vaccine candidates are now being tested (<http://www.aeras.org/candidates/> and <http://www.tbvi.eu/>).

Although important scientific advances have been made recently, major gaps in understanding the basic biology of the organism and the human response to infection with *M. tuberculosis* remain. The rapidly emerging new challenges to the care and control of tuberculosis, such as HIV, MDR tuberculosis, and more recently XDR tuberculosis, may outstrip the advances and threaten our ability to control the disease.

Key Points

- Although tuberculosis cases and case rates are consistently declining in high- and most middle-income countries, the disease continues to be highly prevalent in low- and some middle-income countries.
- The epidemic of HIV infection, especially in sub-Saharan Africa, is leading to extremely high tuberculosis case rates.
- Both HIV infection and resistance to antituberculosis drugs, especially multidrug resistance and extensive

drug resistance, present major problems in worldwide tuberculosis control.

- Adequate treatment for tuberculosis, both drug susceptible and drug resistant, is the major intervention for decreasing transmission of *Mycobacterium tuberculosis*. Treatment consists of an initial *intensive* phase to eliminate actively replicating bacteria quickly followed by a *continuation* phase to eliminate drug-tolerant organisms.
- Assuming an adequate regimen is prescribed, patient adherence is the critical factor that determines the success of treatment.
- The treatment of extrapulmonary tuberculosis is largely the same as the treatment of pulmonary tuberculosis. The exceptions are central nervous system tuberculosis and tuberculosis involving bones and joints, in which treatment of longer duration is recommended.
- Treating latent tuberculous infection in persons at increased risk of progressing to active tuberculosis significantly reduces the risk of disease. Such increased risks include recent conversion of tuberculin skin tests, concurrent HIV infection, chronic renal disease and use of anti-tumor necrosis factor therapy.

eFIGURE IMAGE GALLERY

Figure 35-1 Tuberculosis involving the spine. **A**, Frontal and **B**, lateral chest radiographs show left inferior paraspinal line displacement (*arrow*, **A**) consistent with a posterior mediastinal mass. The lateral chest radiograph shows loss of height of a thoracic vertebral body (*arrowhead*) at this level, but the adjacent intervertebral disc spaces are maintained. Contrast-enhanced axial chest CT displayed in bone (**C** and **D**) and soft tissue (**E**) windows shows lytic vertebral body destruction (*long arrow*, **D**) at the level of vertebral body loss of height seen on the lateral chest radiograph (**B**). Osseous lytic foci are also present in the sternum (*short arrow*, **C**) and posterior ribs (*short arrows*, **C** and **D**). A paraspinal fluid collection with peripheral enhancement, consistent with an abscess (*arrowheads*, **E**) is seen anterior to the involved thoracic vertebral body. Sagittal T2-weighted (**F**) and contrast-enhanced T1-weighted (**G**) and axial T2-weighted (**H**) MR images show the anterior paraspinal abscesses (*arrowheads*), typical of subligamentous spread. Note the extensive high signal within the vertebral bodies (*arrows*, **F**) representing bone marrow edema. The clear vertebral body enhancement (*arrows*, **G**) indicates the presence of osteomyelitis. Note the relative sparing of the intervertebral disc spaces, typical of granulomatous infections and distinct from the common appearance of other causes of bacterial osteomyelitis. Extensive fluid collections are seen in the left erector spinae muscle (*) and involve the adjacent right posterior rib as well. These findings were all the result of tuberculosis. APPENDIX: ESSENTIALS OF CHEMOTHERAPY

INTRODUCTION

The development of successful chemotherapy for tuberculosis must rank as one of the greatest achievements of medical science. Beginning in the late 1940s, chemotherapy began to slow down—little by little—the centuries' long and ever-growing toll from the incurable “captain of all these men of death,” John Bunyan's name for the plague that has killed an estimated 2 billion human beings; more, by far, than any other disease. Notable victims included kings and princes, cardinals, famous poets, writers, musicians, and artists, and, of course, countless anonymous poor people. Finding a cure for this scourge did not happen easily, quickly, or by serendipity. It was the cumulative work over decades by many men and women dedicated to that single purpose, and—keep this in mind—these efforts are ongoing. The history of the initial taming of tuberculosis and why the task remains unfinished makes fascinating reading, especially in the accounts of Dubos and Dubos,¹ Ryan,² and Daniel.³

Even though effective treatment has been available for more than 50 years, tuberculosis continues to plague vulnerable regions of the world. More and more strains of disease-producing *Mycobacterium tuberculosis* are resistant to standard antituberculosis regimens: some strains are resistant to nearly all available agents. The most recent statistics report an estimated 8.6 million new cases and 1.26 million deaths.⁴ Globally, 4% of new cases and 20% of previously treated cases are estimated to have multidrug-resistant tuberculosis (MDR, resistant at least to isoniazid and rifampin).⁵ It is estimated that 9.6% of MDR cases are XDR (MDR to at least one fluoroquinolone and one second-line-injectable drug [amikacin, kanamycin, or capreomycin]) with 96 countries having reported at least one case of XDR.⁵ The overall frequency of pre-XDR (MDR to either fluoroquinolone or second-line-injectable drug) is not known, but studies in convenience samples report between 15%⁶ and 42%^{7,8} of MDR isolates are pre-XDR.

BEGINNINGS

To understand where we currently stand and to appreciate the enormity of the task ahead, this appendix provides a brief chronology of the use of chemotherapy for treating tuberculosis, starting with streptomycin, the original breakthrough agent, which was first injected into a desperately ill young woman in November 1944. To everyone's astonishment and relief, she did not die but slowly began to recover. Then, seemingly miraculously, so did others.⁹

But within a few years, after many more patients with tuberculosis had been treated with streptomycin, it became apparent that the striking clinical and radiographic improvement observed initially did not always last; after several months of treatment, patients began to worsen and the reason was immediately obvious: their tubercle bacilli had become resistant to streptomycin.¹⁰ The findings of clinical failure and emergence of drug resistance served to

define the major bacteriologic principle on which successful chemotherapy for tuberculosis depends: bacillary populations are not uniform in their susceptibility to antituberculosis agents; hence, it is always necessary to treat active disease with more than one drug to which the organisms are susceptible.

The concept of multiple-drug chemotherapy was first validated in 1950 by a British Medical Research Council study in which streptomycin was partnered with *para*-aminosalicylic acid, better known as PAS. Long-lasting success was achieved because PAS prevented organisms from becoming resistant to streptomycin and vice versa, and two drugs have more bacteriologic and clinical effect than only one.¹¹ Since that time, treatment with more than one drug has been standard in the management of patients with tuberculosis. Although the combination of streptomycin and PAS was effective, neither agent was well tolerated and clinical improvement was slow and hampered by side effects. The long-sought solution to antituberculosis chemotherapy arrived in 1952 with the introduction of isoniazid, a powerful drug that was not only highly effective, but well tolerated and inexpensive.¹² However, once again it was learned that single-drug treatment with isoniazid was inadequate because resistance to the agent developed quickly. The solution was clear: combine isoniazid with both streptomycin and PAS. This triple therapy became the standard treatment for tuberculosis until 1967, when a new antituberculosis agent, ethambutol, an easily tolerated and minimally toxic drug, was welcomed as a substitute for PAS.¹³

Subsequent experiments have shown that, in any wild type strain of *M. tuberculosis*, there are subpopulations with spontaneous mutations in genes that confer drug resistance. The frequency of drug-resistant mutants is 1 in 3.5×10^6 for isoniazid, 1 in 3.8×10^6 for streptomycin, 1 in 3.1×10^8 for rifampin, and 1 in 0.5×10^4 for ethambutol.¹⁴ Thus, a bacillary population of more than 10^{12} organisms would be required before one would expect to find (statistically) a single bacillus resistant to both isoniazid and streptomycin.

Once optimum doses of each component were established, wide use of triple therapy revolutionized the care of patients with tuberculosis. Springett¹⁵ reviewed death rates from tuberculosis for cohorts of patients in Birmingham, England, for the years 1947, 1950, 1953, 1956, and 1959. With increasing use of antituberculosis chemotherapy, deaths decreased dramatically during the 10 years after diagnosis, and nearly all of the reduction was accounted for by improvements in survival during the first year after diagnosis. In addition, not only were survivors more numerous, but among survivors, far fewer than in the prechemotherapy era continued to be potential sources of new infections. In the Springett study,¹⁵ both the decrease in mortality rate and the reduction in the prevalence of chronically infectious patients reached their maximum in 1956, with no further improvement in 1959.

The next major advance in chemotherapy for pulmonary tuberculosis resulted from the discovery of rifampin (or

rifampicin, as it is known in many parts of the world) and the demonstration that the combination of isoniazid and rifampin, generally with ethambutol or streptomycin, could dramatically shorten the necessary duration of treatment.¹⁶ In a series of important studies from East Africa during the 1970s, the British Medical Research Council established that a 6-month regimen consisting of isoniazid, streptomycin, and rifampin was as effective as the standard regimen used at the time in developing countries (18 months of isoniazid and thiacetazone, plus streptomycin given during the first 2 months).¹⁷

A critical factor influencing the effectiveness of chemotherapy was, and continues to be, the adherence (or lack thereof) of patients to the prescribed regimen, a fact well documented both in the United States and in developing countries.¹⁸⁻²⁰ In spite of initial high rates of success elsewhere, the results of a U.S. Public Health Service multicenter cooperative trial indicated that a 6-month regimen of isoniazid and rifampin did not have an acceptable rate of favorable outcome.²¹ Positive cultures were found in 6.1% of the patients between 3 and 6 months after treatment began. Of greater importance was that 9.2% experienced relapse after completion of treatment. Strikingly, 16.8% of the patients were withdrawn from the study because they had been delinquent about clinic visits during the 6 months of treatment. This outcome was a setback for efforts to shorten the duration of treatment to 6 months, which—assuming equal effectiveness and tolerance—would have considerable clinical and logistical advantages over 18- to 24-month regimens.

Studies of chemotherapy then began to focus on the possible benefits of pyrazinamide.²² Dickinson and coworkers²³ demonstrated that streptomycin, rifampin, and isoniazid are quickly bactericidal for rapidly growing *M. tuberculosis* in vitro. The in vitro conditions could be likened to the conditions under which the extracellular organisms in tuberculous lesions are living. Although both rifampin and isoniazid are rapidly bactericidal, Mitchison and Dickinson²⁴ demonstrated that rifampin is more effective in killing organisms that grow in spurts rather than continuously. Although both isoniazid and rifampin are effective in killing intracellular organisms, pyrazinamide is especially effective for this purpose, suggesting that the addition of pyrazinamide would strengthen the isoniazid-rifampin combination. Subsequently, two studies substantiated the fact that the addition of pyrazinamide for 2 months to a regimen of isoniazid and rifampin does indeed improve the effectiveness of a 6-month regimen.^{25,26} Thus, a 6-month regimen of isoniazid and rifampin supplemented by pyrazinamide and ethambutol for the initial 2 months is now recommended as standard treatment for most patients with newly diagnosed pulmonary tuberculosis.^{27,28}

DRUGS IN CURRENT USE

As shown in Table 35A-1, 11 drugs currently are approved by the FDA for treating tuberculosis, and 6 other drugs are effective but not approved for this indication. The table lists both first- and second-line drugs, the available preparations, and the doses currently used to treat tuberculosis.

FIRST-LINE DRUGS

Isoniazid is very effective, specific for certain mycobacteria, relatively nontoxic, easily administered, and inexpensive. It is highly active against *M. tuberculosis*: most strains are inhibited by concentrations of 0.05 to 0.20 µg/mL, and it has profound early bactericidal activity. The drug is readily absorbed from the gastrointestinal tract; blood concentrations of approximately 5 µg/mL peak 1 to 2 hours after administration of 3 to 5 mg/kg of body weight. The serum half-life varies depending on whether a person is a rapid or slow acetylator: half-lives are 2 to 4 hours in slow acetylators and 0.5 to 1.5 hours in rapid acetylators.²⁹ The drug penetrates well into all body fluids and cavities, producing concentrations similar to those found in serum.

Isoniazid is a pro-drug and is activated by bacterial KatG, a catalase/peroxidase enzyme.³⁰ Once it is activated, isoniazid inhibits NADH-dependent enoyl-ACP reductase encoded by *inhA*. This process ultimately results in the inhibition of synthesis of essential mycolic acids.³¹ The most common cause of resistance to isoniazid is deletion of or mutations in KatG that result in loss of catalase/peroxidase activity. A mutation in *katG* that results in substitution of threonine for serine in codon 315 (S315T) is the most common mutation found in isoniazid-resistant clinical isolates.^{32,33}

Mutations in the promoter of *inhA* cause resistance to isoniazid and the second-line drug ethionamide.³² These mutations are less frequent than those in *katG*. In a study of clinical isolates collected by the CDC, 82% of the *M. tuberculosis* isolates resistant to isoniazid had a mutation in *katG* only, 6% had mutations in *inhA* only, and 11% had mutations in both.³⁴ Other mutations reported to be associated with isoniazid resistance are mutations in the *furA-katG* intergenic region, as well as in the *oxyR-ahpC* region.³³

When isoniazid is used alone, a population of organisms resistant to the drug emerges rapidly. This was demonstrated in an early clinical trial in which 11%, 52%, and 71% of patients to whom isoniazid alone was given developed resistant strains after 1, 2, and 3 months of treatment, respectively.³⁵

Hepatitis is the major toxic effect of isoniazid.^{28,36,37} Asymptomatic elevations of aminotransferase—up to five times the upper limit of normal—are seen in 10% to 20% of persons receiving isoniazid alone for the treatment of latent tuberculous infection.³⁸ The enzyme levels usually return to normal even with continued administration of the drug. In 11,141 patients managed in an urban tuberculosis control program who were receiving isoniazid alone as treatment for latent tuberculous infection, hepatitis developed in 0.1% to 0.15%.³⁹ A meta-analysis of six studies estimated the rate of clinical hepatitis in patients given isoniazid to be 0.6%.⁴⁰ The rate of clinical hepatitis was 1.6% when isoniazid was given with other agents, *not* including rifampin.⁴⁰ When isoniazid was given in combination with rifampin, the rate of clinical hepatitis averaged 2.7% in 19 reports. For isoniazid alone, the risk increases with increasing age; it is uncommon in persons younger than 20 years old but is nearly 2% in persons ages 50 to 64 years.⁴¹ The risk may also be increased in persons with underlying liver disease, in those with a history of heavy alcohol consumption, and in the postpartum period, particularly among Hispanic women.^{41,42} A large survey estimated the rate of fatal

Table 35A-1 Doses* of Antituberculosis Drugs for Adults and Children†

Drug	Preparation	Adults/ Children	Daily	WEEKLY		
				1×	2×	3×
FIRST-LINE DRUGS						
Isoniazid	Tablets (50 mg, 100 mg, 300 mg); elixir (50 mg/5 mL); aqueous solution (100 mg/mL) for IV or IM injection	Adults (max.)	5 mg/kg (300 mg)	15 mg/kg (900 mg)	15 mg/kg (900 mg)	15 mg/kg (900 mg)
		Children (max.)	10-15 mg/kg (300 mg)	—	20-30 mg/kg (900 mg)	—
Rifampin	Capsule (150 mg, 300 mg). Powder may be suspended for oral administration. Aqueous solution for IV injection	Adults [‡] (max.)	10 mg/kg (600 mg)	—	10 mg/kg (600 mg)	10 mg/kg (600 mg)
		Children (max.)	10-20 mg/kg (600 mg)	—	10-20 mg/kg (600 mg)	—
Rifabutin	Capsule (150 mg)	Adults [‡] (max.)	5 mg/kg (300 mg)	—	5 mg/kg (300 mg)	5 mg/kg (300 mg)
Rifapentine	Tablet (150 mg film coated)	Children	Appropriate dosing for children is unknown			
		Adults	—	10 mg/kg (continuation phase) (600 mg)	—	—
Pyrazinamide	Tablet (500 mg scored)	Children	The drug is not approved for use in children			
		Adults	20-30 mg/kg (2 g)	—	40-50 mg/kg (4 g)	30-45 mg/kg (3 g)
Ethambutol	Tablet (100 mg, 400 mg)	Children (max.)	15-30 mg/kg (2 g)	—	50 mg/kg (4 g)	—
		Adults	15-20 mg/kg (1.6 g)	—	40-50 mg/kg (2.4 g)	25-35 mg/kg (2.4 g)
		Children (max.)	20 mg/kg daily (1 g)	—	50 mg/kg (4 g)	—
SECOND-LINE DRUGS						
Cycloserine	Capsule (250 mg)	Adults (max.)	10-15 mg/kg/day (1 g in two doses), usually 500-750 mg/day in 2 doses [§]	There are no data to support intermittent administration		
		Children (max.)	10-15 mg/kg/day (1 g/day)			
Ethionamide	Tablet (250 mg)	Adults (max.)	15-20 mg/kg/day (1 g/day), usually 500-750 mg/day in a single daily dose or two divided doses	There are no data to support intermittent administration		
		Children (max.)	15-20 mg/kg/day (1 g/day)			
Streptomycin	Aqueous solution (1-g vials) for IM or IV administration	Adults (max.)	15 mg/kg/day (1 g) and 10 mg/kg in persons > 59 years (750 mg). Usual dose 750 mg-1 g IM or IV typically given as a single dose 5-7 days a wk and reduced to 2-3 times a wk after first 2-4 mo or after culture conversion, depending on the efficacy of the other drugs in the regimen			
		Children (max.)	20-40 mg/kg/day (1 g)	—	20 mg/kg	—
Amikacin/ Kanamycin	Aqueous solution (500-mg and 1-g vials) for IM or IV administration	Adults (max.)	15 mg/kg/day (1 g), and 10 mg/kg in persons > 59 (750 mg). Usual dose 750 mg-1 g IM or IV typically given as a single dose 5-7 days a week and reduced to 2-3 times a week after first 2-4 mo or after culture conversion, depending on the efficacy of the other drugs in the regimen			
		Children (max.)	15-30 mg/kg/day (1 g) IM or IV as a single daily dose	—	15-30 mg/kg	—
Capreomycin	Aqueous solution (1-g vials) for IM or IV administration	Adults (max.)	15 mg/kg/day (1 g), and 10 mg/kg in persons > 59 (750 mg). Usual dose 750 mg-1 g IM or IV typically given as a single dose 5-7 days a week and reduced to 2-3 times a week after first 2-4 mo or after culture conversion, depending on the efficacy of the other drugs in the regimen			
		Children (max.)	15-30 mg/kg/day (1 g) as a single daily dose	—	15-30 mg/kg	—

Table 35A-1 Doses* of Antituberculosis Drugs for Adults and Children (Continued)

Drug	Preparation	Adults/ Children	Daily	WEEKLY		
				1×	2×	3×
para-Aminosalicylic Acid (PAS)	Granules (4-g packets) can be mixed with food. Tablets (500 mg) are still available in some countries but not in the United States. A solution for IV administration is available in Europe	Adults Children	8-12 g/day in 2 or 3 doses 200-300 mg/kg/day in 2-4 divided doses (10 g)	There are no data to support intermittent administration		
Levofloxacin	Tablets (250 mg, 500 mg, 750 mg); aqueous solution (500-mg vials) for IV injection	Adults Children	500-1000 mg daily	There are no data to support intermittent administration. The long-term (>several weeks) use of levofloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. However, most experts agree that the drug should be considered for children with tuberculosis caused by organisms resistant to both isoniazid and rifampin. The optimal dose is not known.		
Moxifloxacin	Tablets (400 mg); aqueous solution (400 mg/250 mL) for IV injection.	Adults Children	400 mg daily	There are no data to support intermittent administration. The long-term (>several weeks) use of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.		
Gatifloxacin	Tablets (400 mg); aqueous solution (200 mg/20 mL; 400 mg/40 mL) for IV injection	Adults Children	400 mg daily	There are no data to support intermittent administration. The long-term (>several wk) use of gatifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.		
Bedaquiline fumarate [†]	100-mg tablets	Adults	400 mg administered orally once daily for 2 wk, followed by 200 mg administered orally 3 times weekly, for an entire treatment duration of 24 wk			

Drugs in **bold** are approved by the U.S. Food and Drug Administration for treatment of tuberculosis.

*Dose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as adults.

[†]For purposes of this document, adult dosing begins at age 15.

[‡]Dose may need to be adjusted when there is concomitant use of protease inhibitors or non-nucleoside reverse transcriptase inhibitors.

[§]It should be noted that, although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements are often useful in determining the optimum dose for a given patient.

^{||}The single daily dose can be given at bedtime or with the main meal.

^{††}From Provisional CDC guidelines for the use and safety monitoring of bedaquiline fumarate (Sirturo) for the treatment of multidrug-resistant tuberculosis. *MMWR Recomm Rep* 62(RR-09):1–12, 2013.

Modified from Blumberg HM, Burman WJ, Chaisson RE, et al: American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: treatment of tuberculosis. *Am J Respir Crit Care Med* 167:604–662, 2003; and Francis J, for the Curry National Tuberculosis Center and California Department of Public Health, Drug-Resistant Tuberculosis: A survival guide for clinicians, ed 2. Sacramento, CA, 2008, California Department of Public Health.

hepatitis to be 0.023%,⁴³ but more recent studies suggest the rate is substantially lower.³⁹ The risk may be higher in women. Death has been associated with continued administration of isoniazid well after the onset of symptoms of hepatitis.

Peripheral neuropathy, the second most frequent adverse reaction associated with isoniazid administration, arises especially in persons with other disorders that may cause neuropathy (HIV infection, diabetes mellitus, uremia, and alcoholism). The neuropathy can be prevented or reversed by administration of pyridoxine 25 mg/day.

Rifampin is also rapidly bactericidal for *M. tuberculosis*. The drug is easily administered and is relatively nontoxic. It is quickly absorbed from the gastrointestinal tract; serum concentrations of 6 to 7 µg/mL are reached 1.5 to 2 hours after ingestion. The half-time in blood is 3 to 3.5 hours, although this may be decreased in persons who have been

taking the drug for several weeks.⁴⁴ The half-time increases with increasing doses of the drug. For sensitive strains of *M. tuberculosis*, the minimum inhibitory concentration of rifampin is approximately 0.5 µg/mL, although there is variation among strains.⁴⁵ Approximately 75% of the drug is protein bound, but it penetrates well into tissues and cells. Penetration through noninflamed meninges is poor; however, therapeutic concentrations are achieved in cerebrospinal fluid when the meninges are inflamed.⁴⁶

Among susceptible strains of *M. tuberculosis*, the rate of mutation seems to be less for rifampin than for isoniazid. David¹⁴ reported the rate of mutation to rifampin resistance to be approximately 10×10^{10} per generation. In spite of this rather low rate of in vitro mutation, resistance rapidly develops when rifampin is used alone in vivo.⁴⁷ Resistance to rifampin unaccompanied by resistance to other antituberculosis drugs has been reported to be much more

common among patients with HIV infection, particularly among patients being treated with once- or twice-weekly intermittent regimens containing rifamycins.⁴⁸⁻⁵⁰

Rifampin exerts its effect by binding to the β -subunit of RNA polymerase.³² For this reason, it has activity against many bacteria other than *M. tuberculosis*. Resistance to rifampin results from mutations in the *rpoB* gene, the product of which is the β -subunit of RNA polymerase. Although many different mutations may be involved, alterations in *rpoB*, specifically in a “hot spot” of 81 base pairs (the rifamycin resistance-determining region; RRDR), account for approximately 96% of the rifampin-resistant strains isolated from patients in many different parts of the world.^{27,33,34} The mechanism for resistance in the remaining 4% is not known.

Adverse reactions to daily rifampin include rashes, hepatitis, gastrointestinal upset, and, rarely, thrombocytopenia. The rates of these reactions have been variable, but in general are quite low.²⁸ Hepatitis was a complication in 3.1% of the patients in the U.S. Public Health Service study of 6-month isoniazid-rifampin treatment.²¹ Intermittent (twice-weekly) administration of higher doses of rifampin is associated with several immunologically mediated reactions, including thrombocytopenia, an influenza-like syndrome, hemolytic anemia, and acute renal failure.⁵¹

Drug-drug interactions due to rifampin induction of cytochrome P450 (CYP) enzymes, especially CYPs 1A2, 2C9, 2C19, and 3A4, are common and apply to a broad range of drugs. In the case of tuberculosis, these interactions are especially relevant in patients with HIV infection. The rifamycins—rifampin, rifabutin, and rifapentine—have marked effects on the protease inhibitor and non-nucleoside reverse transcriptase inhibitor classes of antiretroviral agents.²⁸ The interaction of these classes of drugs is bidirectional: protease inhibitors decrease clearance of rifamycins, and rifamycins accelerate metabolism of protease inhibitors by inducing CYP3A4.⁵² Of the rifamycins, rifabutin has the least effect on the concentration of antiretroviral agents. The practical implications of these interactions on treatment regimens are discussed in Chapter 90. Rifampin induces the metabolism of a number of other drugs, including methadone, warfarin, oral contraceptives, digoxin, macrolide antibiotics, and others.²⁸ Doses of these drugs need to be adjusted when rifampin is given. Fluconazole interferes with absorption of rifampin, thereby decreasing its serum concentration.

Rifabutin, although not approved by the U.S. Food and Drug Administration for the treatment of tuberculosis, may be used as a substitute for rifampin in most treatment regimens.²⁸ Because of its lesser propensity to induce cytochrome P-450 enzymes, rifabutin is generally reserved for patients who are taking any medication for which there are unacceptable interactions with rifampin. It may also be used for patients who are intolerant of rifampin. There is extensive cross-resistance among the rifamycins for *M. tuberculosis*. The toxicity profile of rifabutin is similar to that of rifampin except that, in some studies with HIV-infected patients, neutropenia has been reported and uveitis has been described when the drug is given with a macrolide antibiotic that reduces rifabutin clearance.²⁸

Rifapentine, which has the longest serum half-life of the rifamycins, is effective in combination with isoniazid given

once weekly in the continuation phase of treatment for pulmonary tuberculosis.⁵³ However, it should be emphasized that this regimen is *not* to be used for patients with HIV infection, patients who have cavitory lesions on chest film, or patients who have positive sputum smears at the end of the 2-month initial phase of treatment. The toxicity profile is similar to that of rifampin. Rifapentine, given weekly with high-dose isoniazid for a total of 12 doses, is also effective treatment of latent tuberculosis infection.⁵⁴

Ethambutol in usual doses of 15 mg/kg of body weight is generally considered to have a static effect on *M. tuberculosis*. The drug is easily administered and has a low frequency of adverse reactions. Its main effect is to reduce the risk of rifampin resistance in patients with tuberculosis caused by strains that have primary resistance to isoniazid. Peak plasma concentrations are recorded 2 to 4 hours after ingestion. With doses of 15 mg/kg, the peak concentration is approximately 4 μ g/mL.⁵⁵ The concentration increases proportionally with increasing doses. In persons with normal renal function, the half-time in blood is approximately 4 hours. Minimum inhibitory concentrations of the drug for *M. tuberculosis* range from 1 to 5 μ g/mL. Protein binding is minimal, but penetration into cells is thought to be poor. Cerebrospinal fluid concentrations of ethambutol, even in the presence of meningeal inflammation, are low, averaging 1 to 2 μ g/mL after a dose of 25 mg/kg.⁴⁹ Ethambutol appears to exert its effect by interfering with cell wall arabinogalactan biosynthesis. Mutations in the *embB* gene that codes for arabinosyltransferases are found in approximately 70% of ethambutol-resistant strains.³²⁻³⁴

Retrobulbar neuritis is the main adverse effect of ethambutol. Symptoms include blurred vision, central scotomata, and red-green color blindness. This complication is dose related, being in 15% of patients given 50 mg/kg, 1% to 5% of those given 25 mg/kg, and less than 1% in those given 15 mg/kg.²⁸ The frequency of ocular effects is increased in patients with renal failure, presumably owing to increased serum concentrations of the drug.

Streptomycin is rapidly bactericidal, although its effectiveness is inhibited by an acid pH.²⁸ Because the drug is not absorbed from the gut, it must be given parenterally. Peak serum concentrations take place approximately 1 hour after an intramuscular dose. With a dose of 15 mg/kg, the peak concentration is in the range of 40 μ g/mL. The half-time in blood is approximately 5 hours. Sensitive strains of *M. tuberculosis* are inhibited by streptomycin in a concentration of 8 μ g/mL. The drug has good tissue penetration; however, it enters the cerebrospinal fluid only in the presence of meningeal inflammation. Streptomycin and ethambutol have been found to be of approximately equal effectiveness in combination regimens; however, because of a high prevalence of resistance to streptomycin, particularly in patients from developing countries, its usefulness is limited. For this reason and because it requires parenteral administration, streptomycin is no longer considered a first-line agent in treating tuberculosis.²⁸

Streptomycin exerts its effect by interfering with ribosomal protein synthesis. This effect is mediated by binding of the drug to 16S ribosomal RNA (rRNA), thereby inhibiting initiation of translation. Mutations in the genes that code for 16S rRNA (*rrs* and *rpsL*) have been found in 65% to 77% of resistant strains. Mutations in *rpsL* have been

associated with high-level streptomycin resistance, whereas low-level resistance has been associated with *rrs* mutations.³² More recently, mutations in the gene *gidB* were found to be associated with low-level streptomycin resistance.³³ This gene encodes a methyltransferase specific for the 16S rRNA. The available data indicate that *gidB* mutations emerge spontaneously at a high frequency of 10^{-6} .³³

The most serious adverse effect of streptomycin is ototoxicity.²⁸ This usually results in vertigo, but hearing loss is also possible. The risk of ototoxicity is related to cumulative dosage and to peak serum concentrations. In general, peak concentrations of greater than 40 to 50 µg/mL should be avoided, and the total dose should not exceed 100 to 120 g.²⁸ Because of its effect on fetal auditory system development, streptomycin is contraindicated in pregnancy. Streptomycin should be used with caution in patients with renal insufficiency, in whom dosing frequency should be reduced to two to three times a week because of increased risk of nephrotoxicity and ototoxicity.²⁸

Pyrazinamide is active against *M. tuberculosis* at an acid pH, which suggests that the drug is activated under these conditions.⁵⁶ The drug is particularly active against dormant or semidormant *M. tuberculosis* in macrophages or in the acidic environment within areas of caseation and is rapidly bacteriostatic but only slowly bactericidal. Absorption from the gastrointestinal tract is nearly complete; peak serum concentrations take place approximately 2 hours after ingestion. Concentrations generally range from 30 to 50 µg/mL with doses of 20 to 25 mg/kg. The serum half-life is 9 to 10 hours. At a pH of 5.5, the minimal inhibitory concentration of pyrazinamide for *M. tuberculosis* is 20 µg/mL. Penetration of the drug into cells and tissues seems to be fairly good, although data with regard to tissue concentrations are limited.

Recent results indicate that pyrazinamide, after activation by pyrazinamidase to pyrazinoic acid, binds to ribosomal protein S1 (encoded by *rpsA*) and inhibits trans-translation, a mechanism for rescuing protein synthesis on stalled ribosomes.⁵⁷ The genetic mechanism of mycobacterial resistance to pyrazinamide is predominantly due to any of a large number of mutations in the *pncA* gene, which encodes the enzyme pyrazinamidase. This enzyme is necessary for the intracellular conversion of pyrazinamide to its active form, pyrazinoic acid. Mutations in the *pncA* gene are found in approximately 70% to 85% of pyrazinamide-resistant strains.^{32,34,58}

The most important adverse reaction to pyrazinamide is liver injury. This appears to be dose related. In a large U.S. Public Health Service study in which pyrazinamide was given in a dose of 25 mg/kg daily for 6 months, hepatotoxicity developed in 2% to 3% of patients.⁵⁹ At a dose of 40 mg/kg per day, also given for 6 months, 6% of patients developed hepatitis. All patients were also receiving isoniazid and PAS in addition to pyrazinamide. An increased frequency of hepatotoxicity has been reported in studies of pyrazinamide combined with rifampin in a 2-month treatment regimen for latent tuberculous infection in persons without HIV infection; accordingly, the indications for this regimen are limited.

Because pyrazinamide impairs renal urate clearance, hyperuricemia is reported in nearly all patients taking the drug. Clinical gout is not common, but diffuse arthralgias, apparently unrelated to the hyperuricemia, are common.

The drug may also cause nausea and vomiting and skin rashes, especially photosensitive dermatitis.

SECOND-LINE DRUGS

Five additional agents approved for treating tuberculosis are available in the United States: PAS, ethionamide, cycloserine, capreomycin, and bedaquiline. In addition, the fluoroquinolones, amikacin, kanamycin, and linezolid have antituberculosis effects and have been used to a greater or lesser extent, generally in treating patients with tuberculosis caused by drug-resistant organisms. All these second-line drugs have important limitations—effectiveness, toxicity, and cost—that interfere with their general applicability in treating tuberculosis.²⁸

Of the second-line drugs, the fluoroquinolones, levofloxacin and moxifloxacin, are the most widely used because both agents possess good in vitro bactericidal activity and moxifloxacin has good in vivo bactericidal activity against *M. tuberculosis*.^{60,61} The fluoroquinolones are currently not considered as first-line agents but should be reserved either for patients with drug-resistant organisms or those who cannot tolerate first-line drugs.²⁸ Fluoroquinolones are the most important second-line drugs available to treat MDR TB.⁶² Although earlier studies indicated that moxifloxacin substitution for isoniazid or ethambutol resulted in earlier conversion to negative sputum cultures, a recent large phase 3 trial, in which moxifloxacin was substituted for isoniazid or ethambutol in a 4 month regimen for drug-susceptible tuberculosis, revealed a higher relapse rate in patients receiving the moxifloxacin-containing 4 month regimens than in those receiving the standard 6 month regimen.^{62a}

The target of the fluoroquinolones is DNA gyrase, an enzyme that operates to increase coiling of DNA. Resistance to these agents is mediated by mutations in the *gyrA* and *gyrB* genes that encode for DNA gyrase.^{32,33} In a review of 42 studies, 64% of 1220 fluoroquinolone-resistant *M. tuberculosis* isolates had mutations in *gyrA* and 3% had *gyrB* mutations.⁶³

The quinolones are generally well tolerated. The most frequent adverse effects include nausea, vomiting, dizziness, anxiety, and other central nervous system effects. With certain agents, hypoglycemia and hyperglycemia have been observed and some are associated with prolonged QT interval, which can be associated with cardiac arrhythmias. Photosensitivity and arthropathy may also manifest. Although there are multiple small clinical studies of the usefulness of quinolones in multiple-drug regimens, and their oral administration and moderate cost make them attractive agents, their roles in regimens for MDR tuberculosis remain to be established.

Kanamycin, amikacin, and capreomycin are known as the *second-line-injectable* (SLI) drugs. According to current WHO MDR-TB treatment guidelines,⁶⁴ at least one SLI is essential in the 6-month intensive phase of treatment. These drugs are not absorbed from the gastrointestinal tract and thus must be administered parenterally. All three drugs may cause hearing loss related to both peak concentrations and cumulative doses and, in addition, may impair renal function.

Bedaquiline was approved by the FDA in 2012 as part of combination therapy (minimum four drugs) administered

by direct observation to adults 18 years old or older with MDR tuberculosis, when an effective treatment regimen cannot otherwise be provided (i.e., no other drug to which *M. tuberculosis* is susceptible, or drug intolerance).⁶⁵ Bedaquiline is a diarylquinoline and uses *adenosine 5'-triphosphate* (ATP) synthase inhibition as its mechanism of action.⁶⁶ It has in vitro activity against both replicating and nonreplicating bacilli and has bactericidal and sterilizing activity in the murine model of tuberculosis infection. No cross-resistance was found between bedaquiline and isoniazid, rifampin, ethambutol, pyrazinamide, streptomycin, amikacin, or moxifloxacin. Resistance has been observed during clinical studies; bedaquiline has a bacteriostatic effect at low serum levels (0.3 µg/mL) that might predispose to acquired resistance.⁶⁵ Drug-drug interactions exist with CYP3A4 inducers (e.g., rifampin), but their clinical significance is uncertain.⁶⁵

All of the other oral agents are difficult to administer because of adverse effects. It is strongly recommended that consultation with an expert be obtained before treatment with these drugs is undertaken.²⁸ Administration of PAS causes a high frequency of gastrointestinal upset plus hypersensitivity reactions in 5% to 10% of patients. In addition, the usual dose of 10 to 12 g/day requires ingestion of 20 to 24 tablets, although administration has been made somewhat easier by the availability of a granular formulation. Ethionamide likewise causes a high frequency of gastrointestinal side effects, often necessitating discontinuation of the drug. Cycloserine causes behavioral disturbances, ranging from irritability and depression to frank psychosis, in a large percentage of patients taking the drug; seizures and peripheral neuropathy are possible, especially with high doses and when cycloserine and isoniazid are given together. In addition to the adverse effects of PAS, ethionamide, and cycloserine, none of these drugs is particularly potent against *M. tuberculosis*. Other unapproved but possibly useful antituberculosis agents include the β-lactam imipenem, the β-lactam/β-lactamase combination amoxicillin-clavulanate, clofazimine, and linezolid.⁶⁷⁻⁶⁹ These agents have been used in small numbers of patients with tuberculosis caused by MDR organisms. However, their role in the treatment of tuberculosis has not been precisely determined. The currently available compounds of the macrolide class of agents, which are useful against *Mycobacterium avium* complex, do not have antituberculosis effects.

PROGRAMMATIC CONSIDERATIONS

The availability of powerful antituberculosis medications made it possible to cure around 95% of patients with disease caused by susceptible organisms, but it soon became apparent that drugs alone are insufficient; they are but one key element in a comprehensive tuberculosis control program. As far back as 1959, at the landmark Arden House Conference, the basic components of a national public health program were defined with, as a long-range goal, the eradication of tuberculosis in the United States.⁷⁰ Twenty years later, another conference reviewed and refined the objectives and proposed new control strategies.⁷¹ At practically

the same time, effective national tuberculosis control programs were introduced into resource-poor countries by the International Union Against Tuberculosis and Lung Disease⁷²; much later, the concepts that made these programs so efficacious were adopted, updated, and promoted by the WHO under the rubric Directly Observed Treatment Short-course, more familiarly known as DOTS.

Not surprisingly, the lessons from all these activities were similar. Among them, the most important programmatic principle is the obligation of the health care system or treating physician to provide effective supervision of therapy from beginning to end. Because of inadequacies both in the provision of tuberculosis control services and in private physician supervision of treatment, completion of therapy is often problematic.⁷³ As an extreme, at Harlem Hospital in New York during the late 1980s, 89% of patients with tuberculosis who had been started on appropriate treatment were lost to follow-up after discharge, in large part owing to cutbacks in funding of outpatient services.⁷⁴ Obviously, failure to continue medications precludes successful therapy and promotes the emergence of drug-resistant organisms as it did in New York City.

Even in well-organized tuberculosis control programs, ensuring patient adherence to therapy often presents a difficult problem. The reasons for poor adherence are complex and numerous. Prediction of who will be compliant and who will not is difficult and generally unreliable. To improve adherence, a number of modifications in the organization of treatment have been tried, with varying degrees of success.⁷⁵ These include setting clinic hours to suit the patient's schedule; directly observing treatment in the clinic, the patient's home, or another location; and offering incentives and enablers, such as meals and transportation reimbursements.²⁸ Although all of these approaches, as well as others, have had their successes, it is obvious that compliance will remain a major problem as long as treatment regimens continue to be lengthy and cumbersome. It has come to be generally accepted that the best means of ensuring completion of therapy is giving the drugs under *directly observed therapy* (DOT),^{27,28} which is one of the essential elements of the WHO's DOTS global tuberculosis control strategy, mentioned earlier.⁷⁶ The use of the DOTS strategy has been associated with improved treatment outcomes in several cohort analyses.^{20,77,78} However, a Cochrane review of 11 trials with 5609 patients did not show a significant difference in the cure of patients who were treated with observed therapy compared with self-administration.¹⁹ These results highlight the fact that simply observing medication ingestion does not ensure successful completion of treatment and that the full range of measures for supporting patients in completion of treatment must be employed.

Because of heightened public health concerns regarding transmission of *M. tuberculosis* by noncompliant patients and, in particular, concern about MDR organisms, public health statutes that could require DOT or, in some instances, confinement until treatment is completed were strengthened in the early 1990s. A review of the use and usefulness of these laws in New York City has shown that they were not abused and added significantly to the ability of health authorities to improve treatment outcome and minimize spread of tuberculous infection.

INTRODUCTION

Soon after the discovery of *Mycobacterium tuberculosis* in 1882 by Robert Koch, several other species of mycobacteria were described. It was not until half a century later, however, that these mycobacteria were recognized to cause disease in humans, and by the 1980s they were known to cause a broad spectrum of disease.¹ Over the years, these organisms have gone by many names, including “mycobacteria other than tuberculosis,” “environmental mycobacteria,” “anonymous or atypical mycobacteria,” and “*nontuberculous mycobacteria*” (NTM), the preferred term in the United States. The epidemic of the *human immunodeficiency virus* (HIV) heralded a new awareness of NTM infections because of the high rates of disseminated infections due to *Mycobacterium avium* complex² (or, as commonly abbreviated, MAC) and other species.³ Disseminated NTM infections have declined significantly in HIV-infected populations following the advent of antiretroviral drugs whereas rates of NTM disease in HIV-uninfected populations appear to be increasing.

NTM represent a broad array of organisms that are ubiquitous in our environment. They have been isolated from natural and drinking waters as well as soil, and exposure to these reservoirs is thought to be the source of human infection. At least 160 species of NTM have been identified, and many of these have been reported to cause disease in both immunocompetent and immunocompromised patients. Unlike *Mycobacterium tuberculosis*, NTM do not appear to be transmitted from human to human in the absence of extraordinary circumstances, they vary greatly in their ability to cause disease, and evidence for latency is lacking. Unfortunately, NTM are difficult to treat because of high levels of *in vitro* resistance to antimicrobial drugs, which requires long courses of therapy with relatively poor outcomes when compared with tuberculosis. Not surprisingly, these factors result in a treatment cost comparable to other chronic infectious diseases such as HIV infection and *acquired immunodeficiency syndrome* (AIDS).⁴ To date, our lack of understanding of the transmission and pathogenesis of these increasingly important infections has limited our ability to develop public health measures aimed at preventing infection.

MICROBIOLOGY AND TAXONOMY

The genus *Mycobacterium* consists of organisms within the *M. tuberculosis* complex, *Mycobacterium leprae*, and NTM. The latter were classified in 1959 by Runyon into additional groups based on pigmentation in the presence or absence of light (photochromogens, scotochromogens, nonchromogenic) and growth characteristics (slow versus rapid).⁵ All mycobacteria are characterized by their slow rate of growth when compared with other bacterial species, and NTM are further characterized into *rapidly growing* and *slowly growing* organisms: rapid growers can be distinguished by growth in subculture in less than 7 days and slow growers by growth within 2 to 3 weeks. NTM, like all mycobacteria, are also characterized by a thin peptidoglycan layer surrounded by a thick lipid-rich outer membrane.⁶ The lipid-rich outer membrane results in a number of properties that allow the organisms to survive in diverse environments. For example, the hydrophobic cell surface allows surface attachment, resistance to disinfectants and antibiotics, slow growth, and tolerance to heat.⁷ Additional important properties that allow survival in the environment are the ability to grow in low carbon concentrations (oligotroph) and oxygen concentrations.

The availability of molecular methods has rendered the Runyon classification obsolete for clinical purposes and resulted in a marked increase in the identification of new species. In 1997, approximately 50 species of NTM had been identified, with only 13 described as respiratory pathogens.⁸ Currently, there are more than 160 identified NTM species with at least 50 that can be associated with lung infection⁹ (Table 36-1). Thus, it is reasonable to ask why there appears to be such a profusion of NTM species in general and those associated with lung disease in particular.

The primary explanation can be found in the mycobacteriology laboratory. Before the era of high-resolution methods for organism identification, NTM were identified based on their morphologic and biochemical characteristics as well as their *in vitro* susceptibility patterns. The inadequacy or insensitivity of these techniques was reflected in the number of organisms that were grouped as “complexes,” such as the “*Mycobacterium fortuitum* complex,”

Data from Griffith DE, Aksamit T, Brown-Elliott BA, et al: An official ATS/IDSA statement: diagnosis, treatment, and prevention of nontuberculous mycobacterial diseases. *Am J Respir Crit Care Med* 175:367–416, 2007.

which included multiple rapidly growing species such as *M. fortuitum*, *Mycobacterium chelonae*, and *Mycobacterium abscessus*. Although it was apparent that multiple species were present with similar growth and morphologic properties, standard laboratory techniques were not adequate to separate them reliably to the species level.

Currently, there are multiple methods for NTM species identification, including *high-performance liquid chromatography* (HPLC) and DNA probes for the most commonly isolated NTM species.⁹ HPLC has been especially useful in the identification of new NTM species but lacks the sensitivity of molecular techniques. The revolutionary change in NTM identification was the advent of readily available DNA sequencing, especially the sequencing of the 16S ribosomal RNA gene, which is highly conserved so that 1% or greater differences in this gene sequence can define an NTM species. Publicly available databases of 16S ribosomal RNA gene sequences allow rapid comparison of mycobacterial isolates to determine whether a new NTM species is present. Alternatively, sequences of the heat shock protein 65, *rpoB*, *secA* genes or the entire genomic DNA sequence of an NTM species can be compared to other publicly available gene sequence databases.

The expansion of new NTM species in the past 15 years is, therefore, primarily a consequence of higher resolution identification techniques capable of separating closely related NTM species, rather than a proliferation of new NTM species. Predictably, many of these newly identified species have microbiologic properties very similar to those of other closely related NTM, so that identification of the new NTM species may not be associated with any new or surprising clinical properties. It remains to be seen if this revolution in NTM species identification will have an equally profound impact on the understanding of clinical NTM disease. What is certain, however, is that clinicians will need

to become familiar with many more names as new NTM species are identified.

EPIDEMIOLOGY

INCIDENCE AND PREVALENCE

The epidemiology of NTM disease has been difficult to determine because reporting is not mandatory in most countries and differentiation between infection and disease is often difficult. The incidence and prevalence of NTM infections have varied significantly across studies, partially because the studies have used different methodologies and studied different populations.¹⁰ Existing data suggest that the incidence and prevalence of NTM infections are increasing.

Epidemiologic studies of NTM infection and disease use one of three approaches: (1) studying the reactivity to delayed-typed hypersensitivity to mycobacterial antigens; (2) analyzing the reported isolation rate of NTM from laboratories; or (3) using both clinical and laboratory data to define disease more accurately.¹⁰ Studies using delayed-type hypersensitivity reaction to subcutaneously injected mycobacterial antigens have estimated that 11% to 33.5% of the population in the United States have skin test reactivity to NTM.¹⁰⁻¹² A study used data from the National Health and Nutritional Examination Survey cohort to describe skin reactivity to purified protein derivative B during two time periods. For the years 1971–1972 and 1999–2000, rates of a positive skin test were 11.2% and 16.6%, respectively.¹³ Skin test reactivity was noted to increase between the two time periods in foreign-born but not in U.S.-born individuals, suggesting a higher rate of exposure and infection in the foreign-born individuals.

Early laboratory-based studies used consecutive isolates from a well-defined catchment area to estimate the frequency of infection. Survey data from state laboratories in the United States in the early 1980s estimated a prevalence of NTM infection of 1 to 2 cases per 100,000 population.¹⁴ A similar follow-up survey from 1993 to 1996 reported an annual case rate in HIV-uninfected people of 7 to 8 per 100,000, documenting an increase in NTM isolation when compared to the previous survey.¹⁵ These laboratory-based surveys suffer from the fact that they provided isolate-based information but did not take into account the number of patients and whether or not the patients had disease. These early studies have largely been supplanted by better studies based on more rigorous methodologies.

Studies that combine culture and clinical data may be more useful for estimating disease incidence and prevalence. Studies since the 1950s from Czechoslovakia,¹⁶ Wales,¹⁷ Ireland,¹⁸ Australia,¹⁹ and the United States¹⁴ have reported increases in incidence or prevalence. In some reports, the increase in the rate of NTM infection was associated with a decline in the rate of tuberculosis. For example, in Japan from 1971 to 1984, the incidence of pulmonary tuberculosis decreased from 133.1 to 46.3 per 100,000 while the incidence of NTM pulmonary disease increased from 0.89 to 2.15.²⁰ Similarly, in Switzerland, the incidence of pulmonary tuberculosis decreased from 16.2 to 13.2 per 100,000 over 6 years while the incidence of pulmonary NTM increased from 0.4 to 0.9 per 100,000.²¹ In Queensland, Australia, where NTM are reportable, the incidence of clinically significant pulmonary disease rose from 2.2 per 100,000 in 1999 to 3.2 per 100,000 in 2005.²²

The most significant increases in NTM prevalence have been reported from North America. Marras and coworkers²³ reported an increase in the number of pulmonary NTM isolates in Ontario between 1997 and 2003; during this same time period, the rate of isolation of *M. tuberculosis* declined in that province. In a subsequent study, the 5-year prevalence of pulmonary NTM disease in Ontario was reported to increase from 29.3 cases per 100,000 in 1998–2002 to 41.3 cases per 100,000 persons in 2006–2010.²⁴ A recent study reported a significant increase in the annual prevalence of NTM pulmonary disease in patients hospitalized in 11 states between 1998 and 2005²⁵; annual prevalence increased among men and women in Florida (by 3.2 per year and 6.5% per year, respectively) and among women in New York (by 4.6% per year) but there was no significant increase in California. The annual prevalence of NTM pulmonary disease in U.S. Medicare beneficiaries (all 65 years of age and older) increased from 20 per 100,000 in 1997 to 47 per 100,000 in 2007.²⁶ The annual percent change for women was 9.1%, which was significantly higher than that for men (6.4%) (Fig. 36-1). In one particularly rigorous study from Oregon, clinical and radiographic studies from patients with NTM respiratory isolates were evaluated. This study found an overall prevalence of 8.6 cases per 100,000 persons and 20.4 per 100,000 in those at least 50 years of age.²⁷ While not all studies have documented an increase in NTM prevalence,²⁸ the preponderance of evidence suggests that pulmonary disease due to NTM is increasing.

Figure 36-1 Annual prevalence of pulmonary nontuberculous mycobacteria cases among a sample of U.S. Medicare Part B enrollees by gender from 1997 to 2007. NTM, nontuberculous mycobacteria. (Adjemian J, Olivier KN, Seitz AE, et al: Prevalence of nontuberculous mycobacterial lung disease in U.S. Medicare beneficiaries: *Am J Respir Crit Care Med* 185:881–886, 2012.)

The reasons for the increase in incidence and prevalence have not been explained, although increased awareness of the disease and improved diagnostic techniques, especially the widespread application of high-resolution chest *computed tomography* (CT) scanning, could be a factor. A true increase in incidence could be related to changes in the host, such as an aging population, to an increased prevalence of chronic lung disease, or to an increase in the number of immunocompromised individuals. The observation of a decreased incidence of pulmonary tuberculosis and an increased incidence of pulmonary NTM, as noted previously, could be explained by cross-immunity between mycobacterial species. Finally, an increase in the prevalence or virulence of environmental organisms or changes in human behavior that would lead to increased exposure to organisms could be contributing factors.

GEOGRAPHIC DISTRIBUTION AND VARIATION

NTM have been reported to cause pulmonary disease around the globe, although there is marked variation in the prevalence of disease and the predominant species.²⁹ In the United States, the southeastern region has long been considered to have the highest rates of infection.^{14,30,31} NTM have been recovered with higher frequency from water samples in the southeastern versus northern United States, so exposure is likely higher in these regions.³² However, a recent study reported that among Medicare patients, the states with the highest prevalences of pulmonary NTM were Hawaii (396/1000,000) followed by California (191/100,000).²⁶ Florida, Louisiana, and Mississippi also had high prevalences ranging between 151/100,000 and 200/100,000.

The reasons for such geographic variation are not well understood. Pulmonary NTM cases were identified from a nationally representative sample of Medicare Part B

beneficiaries and their counties of residence were divided into low- and high-risk counties in order to identify potential sociodemographic and environmental risk factors.³³ The investigators identified seven clusters of pulmonary NTM cases within high-risk areas constituting 55 counties. The high-risk counties were then compared with 746 low-risk counties. High-risk counties were larger, had greater population densities, and higher education and income levels than the low-risk counties. In addition, high-risk counties had higher mean daily potential for evapotranspiration (the sum of evaporation and plant transpiration of water into the atmosphere) and areas covered by surface water. They were also more likely to have higher copper and sodium and lower manganese levels in the soil. Thus, specific environmental factors correlate with the rates of pulmonary NTM infection.

The predominant species in North America have been MAC, followed by *Mycobacterium kansasii*, *M. abscessus*, *M. fortuitum*, *M. chelonae*, and *M. scrofulaceum*.^{14,30} MAC has also been reported as the predominant species in Central and South America, Europe, and Asia. The predominant species of MAC also varies from region to region. In Europe and South America, *M. avium* is the predominant species whereas *M. intracellulare* is the predominant species in Australia and South Africa.²⁹ *Mycobacterium xenopi* is common in Europe and Canada, whereas *Mycobacterium malmoense* is more common in Northern than Southern Europe. Populations of miners in Czechoslovakia¹⁶ and South Africa^{34,35} have been reported to have high rates of *M. kansasii* infection.

TRANSMISSION AND PATHOGENESIS

TRANSMISSION

NTM are ubiquitous in the environment and have been found in natural and drinking waters, biofilms, soil, and aerosols.³⁶ The presumed source of infection is exposure to these environmental reservoirs because human-to-human transmission has been documented only under extraordinary circumstances.^{37,38} Studies using genotyping techniques, such as pulsed-field gel electrophoresis, *variable number tandem repeat* (VNTR) analysis, and whole genome sequencing have been able to isolate the same strains of NTM from patients and their environments.³⁹⁻⁴¹ Although the mechanism by which an environmental exposure eventually leads to pulmonary infection is poorly understood,⁴² it has been hypothesized that exposure to infected aerosols can lead to infection and possibly disease. In a study to determine whether household plumbing could serve as a source for a patient's NTM isolate, water samples were obtained from the households of 37 patients across the United States.⁴³ Seventeen (46%) of the households yielded at least one mycobacterial isolate of the same species found in the patient and in seven patients, the isolate had the same genotype. In a recent report from Australia, 35% of patients with NTM lung disease had the same species isolated from their home water supply.⁴⁴ In other reports, there are at least two cases that had the same strain of MAC isolated

from the patients' respiratory specimens and water from their shower head.^{39,40} In another report, the patient's strain of MAC was isolated from potting soil in the home.⁴¹ There have also been reports of outbreaks in which patients' isolates matched environmental isolates of NTM.⁴⁵ In a recent study using interviews of HIV-negative adults with MAC, aerosol-generating activities and home and garden water supply features were not found to be risk factors but prior lung disease and immune-suppressing drugs were.⁴⁶

Until recently, person-to-person transmission was considered an unlikely mode of transmission.⁴⁷ However, two recent studies have described possible transmission in *cystic fibrosis* (CF) clinics.^{37,38} The first report described a potential outbreak of *M. abscessus* subsp *massiliense* in a CF clinic in Seattle.³⁷ A smear-positive patient may have transmitted infection to four other patients with CF at the same clinic; the infecting strain was indistinguishable by pulsed-field electrophoresis and polymerase chain reaction analysis. An additional report from the United Kingdom also described transmission of *M. abscessus* subsp *massiliense* at a CF center.³⁸ The authors noted that direct person-to-person transmission was unlikely but that cross infection in the hospital setting was likely.

Extrapulmonary NTM infections in immunocompetent patients are usually the result of a puncture wound or surgery. A recent outbreak of skin and soft tissue infections due *M. abscessus* subspecies *massiliense* involved more than 2000 patients who had undergone invasive procedures such as laparoscopic, arthroscopic, plastic, or cosmetic surgery.⁴⁸

FACTORS ASSOCIATED WITH INFECTION

A prospective study using skin testing data from Palm Beach, Florida, reported that 32.9% of 447 participants in a population-based random household survey had a positive reaction to *M. avium* antigens.⁴⁹ Independent predictors of a positive reaction included black race, birth outside the United States, and more than 6 years' cumulative exposure to soil. Exposure to water, food, and pets was not associated with skin test reactivity. Using National Health and Nutritional Examination Survey data, investigators reported similar findings with regard to sensitization to *Mycobacterium intracellulare*¹³; male gender, non-Hispanic black race, and birth outside the United States were each independently associated with sensitization. The highest rate of skin test reactivity was found in persons who were 20 to 39 years of age; among individuals 20 years of age and older, working in agriculture or construction was strongly associated with sensitization. These two studies are interesting in that skin test reactivity to either *M. avium* or *M. intracellulare* antigens was associated with factors likely associated with soil exposure and were more common in men and foreign-born individuals. However, disease seems to be more common in older women and, at least in the United States, in U.S.-born. Additionally, the source for *M. avium* infection, frequently associated with nodular/bronchiectatic MAC lung disease, appears to be primarily municipal (tap) water in the United States, whereas *M. intracellulare* infection is acquired through some other source, likely soil.⁵⁰ Thus, it is likely that the risk factors for infection are different from those associated with disease.

FACTORS ASSOCIATED WITH DISEASE

Most NTM are significantly less pathogenic than *M. tuberculosis* and likely require some degree of host impairment to establish disease. A number of risk factors for disease have been described, and these can be subdivided broadly into three groups: (1) factors impairing host immunity, (2) factors leading to impaired local (lung) immunity, and (3) factors relating to the species. These factors can be reduced further into the “unusual dose” model and “susceptible person” model.⁴⁶ In the “unusual dose” model, it is postulated that individuals who become infected do so because of an unusually large exposure to NTM, whereas in the latter model, it is assumed that some susceptibility is necessary for infection to manifest. It is likely that, in most patients, both models of pathogenesis are at play to varying degrees.⁵¹

Increasing age has been consistently described as a risk factor for pulmonary NTM, in patients both with and without underlying lung disease.^{12,14,52,53} The most consistently reported risk factor is male gender, though there is also a population of elderly females who are at risk for nodular bronchiectatic lung disease. Perhaps the most important risk factor for the development of pulmonary NTM disease is underlying chronic lung disease. NTM disease has been described in association with CF, chronic obstructive pulmonary disease (including α_1 -antitrypsin deficiency), cavitory lung disease, pneumoconiosis, bronchiectasis, prior tuberculosis, and pulmonary alveolar proteinosis.⁵⁴ Studies have documented a high prevalence of NTM in sputum cultures from patients with CF, with estimates ranging from 3% to 19.5% prevalence of NTM, the majority of which were MAC.^{55,56}

Patients with NTM lung disease often have associated *gastroesophageal reflux disease* (GERD) or other esophageal disorders. Historically, it has been reported that patients with *rapidly growing mycobacteria* (RGM) often have associated esophageal disorders⁵⁷⁻⁵⁹; recent reports have reported that patients with lung disease due to MAC, a slow grower, also have a high frequency of GERD.^{60,61} In a report from South Korea that used pH probes to diagnose GERD, the authors reported that the prevalence of GERD was 26%, although only one fourth of these patients had typical GERD symptoms.⁶⁰ Patients with *M. abscessus* infection were more likely to have GERD than those with MAC, although the difference did not reach statistical significance.

An interesting patient population with NTM pulmonary disease consists of postmenopausal women who often have certain associated morphologic features. This constellation was first described by Prince and colleagues⁵² in 1989 and later referred to as the “Lady Windermere syndrome,” after the lead in Oscar Wilde’s play *Lady Windermere’s Fan*, who was characterized by her fastidious behavior in actively suppressing a chronic cough.⁶² The morphologic features such as pectus excavatum, scoliosis, thin body habitus, and mitral valve prolapse were described subsequently by Iseman and others.⁶³ Recently, investigators reported that women with pulmonary NTM disease were taller and thinner and weighed less than matched control subjects⁶⁴ (Fig. 36-2): 51% had scoliosis, 11% pectus excavatum, and 9% mitral valve prolapse, all significantly more common than in reference populations. Another feature of this syn-

drome is the predilection for right middle lobe and lingular bronchiectasis. To date, extensive evaluation of the immune system of these patients has shown mixed results, but mutations in the *CF transmembrane conductance regulator* (CFTR) gene are common.⁶⁴⁻⁶⁶ Among 103 women with pulmonary NTM, some intriguing cytokine relationships were found to be abnormal: compared with the findings in uninfected control subjects,⁶⁶ in those with NTM, the normal relationship between the adipokines, leptin and adiponectin, and body fat was lost and *interferon- γ* (IFN- γ) and *interleukin* (IL)-10 levels were significantly suppressed in stimulated whole blood. These intriguing in vivo and in vitro findings suggest a predisposing immunophenotype for NTM.

NTM in AIDS most commonly causes disseminated disease that presents with nonspecific symptoms such as fever, night sweats, diarrhea, abdominal pain, and lymphadenopathy, with MAC being the most frequent isolate⁶⁷ (also see Chapter 90). Despite isolation of MAC from the sputum in up to 10% of AIDS patients with CD4 T-cell counts less than 50 cells/ μ L, pulmonary disease due to MAC is uncommon.⁶⁸ Pulmonary disease has been reported in 2.5% to 8% of patients with disseminated MAC⁶⁹ and has rarely been reported in the absence of dissemination.^{69,70} Patients with pulmonary disease tend to have higher CD4 counts and focal alveolar opacities, which rarely cavitate. *Mycobacterium kansasii* can also cause disease in patients with HIV and AIDS. In one study, the risk for infection with *M. kansasii* was increased 150-fold in HIV-infected patients and 900-fold in those with AIDS.⁷¹ In contrast to MAC, *M. kansasii* should always be treated as a potential pathogen.⁷²

Pulmonary disease due to NTM has been described in several other immunocompromised populations, including transplant recipients. Rates may be as high as 6.5% following heart or lung transplantation,⁷³ and 2.9% following bone marrow transplantation,⁷⁴ but are probably much lower in patients following liver or kidney transplantation.^{75,76} *M. abscessus* infection in patients with CF who have undergone lung transplantation has been associated with severe and sometimes fatal disease.⁷⁷⁻⁷⁹

Multiple cytokines are necessary for containment of mycobacterial infections. The most important among these are IFN- γ , IL-12, and tumor necrosis factor. Patients with defects in any of these cytokines are susceptible to infection with NTM. Mutations in the genes that code for *IFN- γ receptor 1* (IFN- γ R1), IFN- γ receptor 2, IL-12 p40, and the IL-12 receptor have all been shown to lead to human disease.⁸⁰ The dominant and recessive IFN- γ R1 deficiencies have distinct clinical presentations.⁸⁰ The adult onset immunodeficiency that can result from the development of autoantibodies against IFN- γ is associated with severe disseminated opportunistic infections including NTM.⁸¹ Mutations in *GATA2* are associated with autosomal dominant and sporadic monocytopenia and disseminated mycobacterial infections called the MonoMAC syndrome.⁸² Large numbers of patients with inflammatory bowel disease, rheumatoid arthritis, or psoriatic arthritis are treated with tumor necrosis factor inhibitors. Although initially shown to predispose to tuberculosis,⁸³ recent reports have linked these therapies to NTM infections as well.⁸⁴ Patients with suspected or known mycobacterial infections should not receive these

Figure 36-2 Schematic depiction of the anthropometrics of women with pulmonary nontuberculous mycobacterial disease (n = 60) (left) compared with National Health and Nutrition Examination Survey age-, gender-, and race-matched control subjects (right). (Reproduced with permission from Kim RD, Greenberg DE, Ehrmantraut ME, et al: Pulmonary nontuberculous mycobacterial disease: Prospective study of a distinct preexisting syndrome. *Am J Respir Crit Care Med* 178:1006–1074, 2008.)

medications without proper antimycobacterial therapy. A potential risk factor for NTM lung infection in CF patients is the prolonged use of azithromycin, which inhibits autophagy, an intracellular mechanism that constrains mycobacterial infection.⁸⁵ Prolonged exposure to azithromycin in this context can also select for macrolide resistance in MAC.

Although most studies have focused on evaluating possible host abnormalities that could lead to NTM disease, microbial factors are likely to be important as well. Recent studies have identified isolates and phenotypes associated with increased virulence in *in vitro* models.^{86–88} *M. abscessus* is known to exist in a smooth and rough phenotype. Limited clinical data as well as data from mouse models suggest that the rough may be more virulent than the smooth phenotype. It has been reported that the presence of glycopeptidolipids on the smooth strains mask agonists of Toll-like receptor 2 and prevent induction of the proinflammatory cytokine, tumor necrosis factor, allowing the organisms to colonize and form biofilms in the lung airways.⁸⁵ If the organism then switches to a rough phenotype, the glycopeptidolipids are lost, allowing the strain to elicit an inflammatory response that paradoxically promotes invasive infection. Moreover, a recent population-based assessment of the clinical significance of NTM in a region of The Netherlands demonstrated a wide range of pathogenicity among different NTM species.⁸⁷

Table 36-2 Diversity of Nontuberculous Mycobacteria Pulmonary Disease

- Tuberculosis-like (cavitary) disease
- Disease associated with nodules/bronchiectasis
- Disease associated with genetic airway abnormalities and abnormal airway clearance (cystic fibrosis, primary ciliary dyskinesia, alpha₁-antitrypsin deficiency)
- Hypersensitivity-like lung disease
- Disease associated with esophageal motility disorders
- Disease associated with disseminated disease and immune suppression
- HIV/AIDS
- Defects in interferon- γ and interleukin-12 pathways
- Disease associated with treatment with tumor necrosis factor- α antagonists

DIAGNOSIS AND MANAGEMENT OF SPECIFIC PATHOGENS

NTM lung infection presents with diverse manifestations (Table 36-2). This chapter focuses on the most common clinical presentations in the immunocompetent hosts: chiefly, tuberculosis-like (cavitary) disease and disease associated with nodules and bronchiectasis (nodular/bronchiectatic disease). The diagnostic evaluation usually

consists of (1) assessment for the presence of one or more compatible symptoms, which are usually insidious in onset (cough, sputum production, fatigue, weight loss, fever, hemoptysis); (2) radiographic evaluation, which frequently includes *high-resolution computed tomography* (HRCT) scans of the chest; and (3) microbiologic evaluation, which usually consists of three or more sputum specimens for microscopy and mycobacterial culture and/or collection of specimens bronchoscopically. The most important diagnosis to exclude is tuberculosis. Additional laboratory evaluation aimed at identifying potential reasons for the underlying infection may include testing for CF, α_1 -antitrypsin deficiency, primary ciliary dyskinesia, or esophageal disorders in patients with pulmonary disease and, in the case of disseminated disease, the presence of cell-mediated immunodeficiency or anti-IFN- γ autoantibodies.

The diagnosis of NTM lung disease can be challenging. Unlike pulmonary tuberculosis, in which, barring laboratory contamination, a single positive culture of sputum or of a bronchoscopic specimen establishes the diagnosis, confirmation of the diagnosis of NTM lung disease usually requires repeated isolation of a particular NTM species. Diagnostic criteria have been developed to aid the clinician in the evaluation of persons suspected of having pulmonary NTM disease.⁹ The NTM diagnostic criteria outlined in Table 36-3 are based on experience with common and well-described respiratory pathogens such as MAC, *M. kansasii*, and *M. abscessus*. However, it is important to note that, because of the varying pathogenicity among the many NTM species, no single diagnostic approach will work for all cases.⁸⁷ Diagnostic criteria that are too sensitive promote overdiagnosis and the unnecessary exposure of patients to potentially toxic antimicrobial medications. By contrast, overly rigid diagnostic criteria put patients at risk for undertreatment and progressive NTM disease. Fortunately, NTM lung disease is usually sufficiently indolent that there is usually time for a careful assessment to determine with confidence the presence or absence of significant disease.

The difficulty in determining the clinical significance of an NTM respiratory isolate results from several factors. NTM isolates can contaminate clinical specimens, usually

from environmental sources. Many NTM species, such as *Mycobacterium gordonae*, are generally nonpathogenic and almost invariably represent specimen contamination rather than true infection. NTM can be found in potable (municipal or tap) water (*M. kansasii*, MAC, *Mycobacterium simiae*, *M. abscessus*, *M. xenopi*), so that their presence in a clinical specimen can be due to waterborne contamination of the specimen, even if the isolated species is one that is capable of causing clinical disease. The recovery of even potentially virulent and pathogenic NTM may be associated with the absence of active or progressive disease, for reasons that are not understood. Unfortunately, no easily applied algorithm addresses all NTM species in all clinical circumstances. The clinician must have some knowledge of the disease-producing potential of NTM species and also an awareness of the circumstances associated with the isolation of the NTM species.

A single positive sputum culture for NTM is usually regarded as indeterminate for the diagnosis of NTM lung disease. In contrast, when two or more sputum cultures are positive, the diagnosis of disease is more likely. For example, 98% of patients with two or more positive sputum cultures for MAC had evidence of progressive disease during follow-up.⁸⁹ A single positive NTM culture from bronchoscopy can be diagnostic for disease (see Table 36-3), so repeated bronchoscopy is not appropriate if its only purpose would be to obtain multiple positive cultures. However, the clinician must keep in mind those NTM species that are usually respiratory contaminants (especially *M. gordonae*) and those NTM species that can be found in tap water (discussed earlier) since “pseudo-outbreaks” of NTM disease can be the consequence of bronchoscopic equipment that has been inappropriately rinsed with tap water.⁹⁰ Patients who are suspected of having NTM lung disease but do not meet the diagnostic criteria should be followed clinically until the diagnosis is either firmly established or excluded, a process that can take months to years.

Diagnosis of NTM lung disease does not necessitate the institution of therapy, which is a decision based on potential risks and benefits of therapy for individual patients. Factors that might influence the decision to treat NTM lung disease include the virulence of the NTM pathogen and the potential for disease progression, the severity (or lack of severity) of symptoms and radiographic findings, the presence of known indolent disease, and the presence of advanced age and/or severe comorbid conditions (with limited life expectancy); another factor is the inability to tolerate the prolonged and sometimes toxic antimicrobial regimens for NTM disease. Again, for optimal management of NTM lung disease, there is no substitute for physician familiarity with NTM pathogens and with the individual patient.

Other clinical manifestations of NTM infection include lymphadenitis, disseminated disease, and skin, soft tissue, and bone disease. Lymphadenitis is the most common NTM disease manifestation in children and is usually due to MAC or, less commonly, *Mycobacterium haemophilum* or *M. scrofulaceum*.⁹¹ The most important differential diagnosis is tuberculosis lymphadenitis, although NTM account for approximately 90% of mycobacterial lymphadenitis in American children (but only 10% in adults).⁹² Symptoms are usually minimal, with frequent unilateral involvement of submandibular, submaxillary, preauricular, or cervical

Table 36-3 Microbiologic Criteria for Diagnosis of NTM Lung Disease

Specimen	Results
At least three sputum results available with: or	Two positive cultures regardless of the results of AFB smear
Single available bronchial wash or lavage with: or	One positive culture regardless of the results of AFB smear
Tissue biopsy with:	Compatible histopathology (granulomatous inflammation) and a positive biopsy culture for NTM Compatible histopathology (granulomatous inflammation) and a positive sputum or bronchial wash culture for NTM

AFB, acid-fast bacilli; NTM, nontuberculous mycobacteria.

Data from Griffith DE, Aksamit T, Brown-Elliott BA, et al: An official ATS/IDSA statement: Diagnosis, treatment, and prevention of nontuberculous mycobacterial diseases. *Am J Respir Crit Care Med* 175:367–416, 2007.

lymph nodes. Skin and soft tissue infections are usually due to the “rapidly growing mycobacteria,” *M. abscessus*, *M. fortuitum*, *M. chelonae*, or *M. marinum*, and are the result of direct inoculation after either trauma or surgery.^{1,93} Dissemination of NTM pathogens is most often associated with the severe immunosuppression of advanced AIDS and is caused by MAC.^{67,94-96} Disseminated NTM infections can be seen in other immune-compromised states, such as organ transplantation, autoantibodies to IFN- γ , or in association with indwelling foreign bodies such as venous catheters, dialysis catheters, or other prosthetic devices.⁹⁷⁻¹⁰⁰

LABORATORY DIAGNOSIS

The diagnosis of NTM disease is based on isolation of these organisms from clinical specimens. Cultures should include both solid and broth media for sensitive detection of mycobacteria and, ideally, a semiquantitative reporting of colony counts.⁹ The optimal temperature for growth of most NTM species is between 28°C and 37°C, although some species require either higher or lower temperatures for optimal growth and some species require special supplementation for recovery from culture.⁹ Most NTM grow within 2 to 3 weeks of subculture but the group of rapidly growing NTM appear within 7 days of subculture.

Identification of specific species can be based on phenotypic, chemotaxonomic, and molecular methods.⁹ NTM can be categorized by their growth rate and pigmentation, although these characteristics are not specific enough for final speciation. In addition, biochemical testing can be used to help speciate the NTM. However, none of these procedures is sufficient to differentiate all NTM, particularly some of the newly identified species.

Additional techniques for speciation include HPLC, nucleic acid probes, polymerase chain reaction and other amplification methods, and nucleic acid sequencing.¹⁰¹⁻¹⁰⁶ HPLC, which analyzes the chromatographic profile of the mycolic acids extracted from the bacterial cell wall, can be used to speciate a large number of NTM.¹⁰⁷ Identification of mycobacteria by 16S ribosomal DNA sequencing^{101,102} provides more accurate determination of the species, although neither HPLC nor 16S ribosomal DNA sequencing can differentiate all species of NTM. The commercially available AccuProbe technology (Gen-Probe, San Diego, CA) is currently recommended for identification of *M. tuberculosis* complex, *M. avium* complex (as well as *M. avium* and *M. intracellulare* separately), *M. kansasii*, and *M. goodii*.

The clinical usefulness of drug susceptibility testing in the management of patients with NTM disease remains controversial because in vitro results do not correlate well with clinical outcomes for some mycobacterial species. For slowly growing mycobacteria, no single susceptibility method is recommended for all species. For MAC, a broth-based culture method—with both microdilution and macrodilution methods—is considered acceptable.⁹ Initial isolates should be tested for response to clarithromycin, as should isolates from treatment failures and relapses, from patients who have taken macrolides previously, and from AIDS patients who develop bacteremia on macrolide prophylaxis. For *M. kansasii*, isolates should be tested for response to rifampin (rifampicin) because resistance to rifampin is associated with treatment failure or relapse. If

rifampin resistance is documented, additional drugs should be tested.⁹ For RGM, broth microdilution minimal inhibitory concentration determination for susceptibility testing is recommended.

SLOWLY GROWING MYCOBACTERIA

Although there are fewer species of slowly growing NTM than rapidly growing species, the slow growers are more common causes of lung disease (see Table 36-1). The slow growers include more than 70 species with a wide range of pathogenicity, from organisms such as *M. kansasii* that are probably second only to *M. tuberculosis* in terms of disease-producing capability to *M. goodii*, which rarely causes lung disease.

Mycobacterium avium Complex

Mycobacterium avium complex includes the NTM species *M. avium*, of which there are several subspecies, *M. intracellulare*, *M. chimaera*, *M. colombiense*, and *M. vulneris*, as well as some less well-described species. As noted previously, *M. avium* and *M. intracellulare* are likely acquired from different environmental sources. Differentiation of the separate MAC species is not possible with routine laboratory techniques, although DNA probes are available for *M. avium* and *M. intracellulare*. Currently, in most circumstances, the differentiation of *M. avium* and *M. intracellulare* does not make a significant difference clinically or therapeutically (although *M. avium* is more often seen with disseminated disease and, in the United States, *M. intracellulare* is more often isolated as a respiratory pathogen). However, recent data from South Korea suggest that *M. intracellulare* may be more virulent than *M. avium*: compared to those with *M. avium*, patients with *M. intracellulare* presented with more severe disease and had a worse prognosis.¹⁰⁸

MAC lung disease typically presents as apical fibrocavitary lung disease similar to tuberculosis, sometimes with large cavities, usually in males but also in females in their fifth and sixth decades who have a history of cigarette smoking and alcohol abuse (Fig. 36-3). If left untreated, this form of disease is generally progressive, can result in extensive cavitary lung destruction, and is associated with increased mortality compared with noncavitary MAC lung disease.¹⁰⁹⁻¹¹¹ The necessity for starting therapy with cavitary MAC lung disease is clearly much more pressing than with noncavitary MAC disease.

MAC lung disease also presents with nodular and interstitial nodular opacities, which frequently involve the right middle lobe or lingula, predominantly in postmenopausal nonsmoking white females (Fig. 36-4; eFig. 36-1). This form of disease, termed *nodular/bronchiectatic disease*, tends to have a much slower progression than cavitary disease, so that long-term follow-up may be necessary to demonstrate clinical or radiographic changes. Even with this more indolent form of disease, however, death may result from progressive disease.⁵² Nodular/bronchiectatic MAC lung disease is radiographically characterized by HRCT findings that include multiple small peripheral bronchiolocentric pulmonary nodules with branching configurations, and cylindrical bronchiectasis (see Fig. 36-4; see eFig. 36-1). The HRCT pattern of these predominantly peripheral small nodular branching opacities has been described as

Figure 36-3 A 63-year-old female smoker with cavitary *Mycobacterium avium* complex (MAC) lung disease. The patient, who presented with cough, fatigue, weight loss, and intermittent hemoptysis, was diagnosed with MAC in 2004. She failed two courses of multidrug therapy and, at the time of this imaging, her sputum was still culture positive for MAC. **A**, Chest radiograph showing cavitary consolidation in the right apex and scattered nodular and reticulonodular opacities in both lungs. **B**, Axial chest CT shows a large right apical cavity.

“tree-in-bud,” and reflects inflammatory changes including bronchiolitis.

Patients with nodular/bronchiectatic MAC lung disease often have additional microbiologic findings associated with bronchiectasis, including respiratory cultures positive for *Pseudomonas aeruginosa*, *Nocardia* species, and occasionally other NTM such as *M. abscessus*. Because nonmycobacterial exacerbations of bronchiectasis often complicate the assessment and management of MAC disease, strategies aimed at treatment of the bronchiectasis may improve patients’ symptoms.

For many patients, perhaps the majority of patients with nodular/bronchiectatic disease, it is unknown if bronchiectasis is the result of the mycobacterial infection or if bronchiectasis due to some other process then predisposes to subsequent mycobacterial infection. In some patients with NTM lung disease, bronchiectasis is clearly the result of diseases such as CF, primary ciliary dyskinesia, or α_1 -antitrypsin deficiency and thus antedates the MAC disease.^{65,112,113} The routine evaluation of underlying causes

of bronchiectasis, such as CF and α_1 -antitrypsin deficiency, in patients with nodular/bronchiectatic MAC disease is currently controversial and no consensus exists.

Therapy of MAC Lung Disease. Several aspects of treatment for MAC lung disease are difficult to explain, and even counterintuitive. The greatest misunderstanding about treatment regimens for NTM pathogens results from the expectation that all NTM infections should respond in a predictable manner to antimicrobial therapy, similar to infections due to *M. tuberculosis*. However, even when treatment regimens are based on in vitro susceptibility testing, the NTM pathogen very often does not respond to antimicrobial agents as predicted from the susceptibility results. The most difficult and frustrating aspect of NTM therapy for many clinicians is the lack of a clear association between the in vitro susceptibility results and the in vivo, clinical response. For many NTM, including MAC, laboratory cutoffs for “susceptible” and “resistant” do not have a demonstrable clinical correlate and have not been confirmed to be clinically meaningful. Response to treatment of disease caused by MAC correlates primarily with in vitro susceptibility to macrolides (clarithromycin and azithromycin), and not to most other agents.¹¹⁴⁻¹¹⁹ However, evidence is emerging that in vitro susceptibility or resistance to amikacin does impact the outcomes of treatment regimens that include amikacin.¹²⁰ Several other NTM species (e.g., *M. abscessus*, *M. simiae*, *M. malmoense*, *M. xenopi*) lack established correlation between in vitro susceptibilities and in vivo responsiveness to any antimicrobial agent. The reason for the discordance between laboratory susceptibility testing results and clinical benefit for many NTM is not known. Accordingly, clinicians must use in vitro susceptibility data for many NTM with the awareness that the results are an imperfect guide to treatment outcome. Two recent reviews summarize the multiple and complicated factors that likely impact this troubling aspect of NTM disease therapy.^{121,122}

Because the macrolides—clarithromycin and azithromycin—are the principal and most important antimicrobial agents for which there is a demonstrated correlation between in vitro susceptibility and in vivo response for MAC lung disease, these agents, partnered with ethambutol, serve as the cornerstones of MAC therapy (Table 36-4). As also shown, this regimen must be reinforced with a rifamycin and, possibly, an injectable aminoglycoside (amikacin or streptomycin), because companion drugs are necessary to prevent the emergence of macrolide-resistant MAC isolates. Macrolides should never be used as monotherapy for treatment of MAC disease, either pulmonary or disseminated.¹²³

An additional phenomenon associated with MAC drug therapy is that patients who have failed prior MAC therapy, with or without a macrolide, have lower sputum conversion rates with macrolide-containing treatment regimens, even with macrolide-susceptible MAC isolates, than do patients with no prior therapy.^{115,118,124,125} Although the explanation for this is not clear, it is evident that the best chance for treatment success in MAC lung disease is the first treatment effort. Finally, patients who are successfully treated for nodular/bronchiectatic MAC disease can be reinfectd by new MAC isolates, sometimes with renewal of progressive disease.¹²⁶

Figure 36-4 Chest radiographs and CT scans of two women with MAC lung disease. **A and B,** A 60-year-old female nonsmoker with several years of chronic cough and “recurrent pneumonia.” Sputum was acid-fast bacilli (AFB) smear positive and culture positive for MAC at the time of the radiograph and on multiple subsequent collections. **A,** Frontal chest radiograph shows primarily mid and lower lung nodular and reticulonodular abnormalities. **B,** High-resolution chest CT from this patient shows bilateral bronchiectasis with variably sized centrilobular nodules, some showing a branching configuration, consistent with nodular “tree-in-bud” pattern. **C and D,** A 74-year-old woman with more than 20 years of cough with sputum production, “recurrent pneumonia,” severe fatigue, and weight loss. Sputum is strongly AFB smear positive and culture positive for MAC on multiple collections. **C,** Frontal chest radiograph shows multifocal bilateral bronchial wall thickening and dilation and nodular opacities. **D,** High-resolution chest CT from this patient shows extensive severe multilobar bronchiectasis.

Table 36-4 Treatment of Pulmonary Disease due to <i>Mycobacterium avium</i> Complex Infections	
Type of Disease	Regimen
Nodular/bronchiectatic disease	1. Clarithromycin 1000 mg tiw or azithromycin 500 to 600 mg tiw and 2. Ethambutol 25 mg/kg tiw and 3. Rifampin 600 mg tiw
Cavitary disease	1. Clarithromycin 500 to 1000 mg/day or azithromycin 250 to 300 mg/day and 2. Ethambutol 15 mg/kg daily and 3. Rifampin 450 to 600 mg daily and 4. Consider streptomycin or amikacin 15 mg/kg tiw for first 2 to 3 months
Advanced or previously treated disease	1. Clarithromycin 500 to 1000 mg/day or azithromycin 250 to 300 mg/day and 2. Ethambutol 15 mg/kg daily and 3. Rifabutin 150 to 300 mg daily or rifampin 450 to 600 mg daily and 4. Include streptomycin or amikacin 15 mg/kg tiw for first 2 to 3 months

tiw, three times per week.
Data from Griffith DE, Aksamit T, Brown-Elliott BA, et al: An official ATS/IDSA statement: Diagnosis, treatment, and prevention of nontuberculous mycobacterial diseases. *Am J Respir Crit Care Med* 175:367–416, 2007.

The recommended duration of treatment for MAC pulmonary disease is to continue therapy until 12 months of sputum culture negativity,⁹ a goal that requires patients to have sputum collected for mycobacterial culture on a regular basis throughout the course of treatment.

For some patients who are taking clarithromycin, the doses may need to be split (e.g., 500 mg twice daily) because of gastrointestinal intolerance. For patients of low body weight (<50 kg) or older age, the clarithromycin dose for daily regimens may need to be reduced to 500 mg/day or 250 mg twice daily because of gastrointestinal intolerance. However, it should be noted that, in a small (*N* = 34) three-arm retrospective study from Japan, 400 mg daily was associated with a lower sputum conversion rate at 18 months than 800 mg daily.¹²⁷ Patients receiving clarithromycin and rifabutin should be carefully monitored for rifabutin-related toxicity, especially hematologic (leukopenia) and ocular (uveitis) toxicity. For some patients, especially those with nodular/bronchiectatic MAC disease, intermittent or three times weekly therapy may facilitate tolerance of the multi-drug MAC treatment regimen and is associated with a high treatment success rate.^{127a}

Macrolide-resistant MAC lung disease is associated with a poor prognosis.¹²³ The two major risk factors for macrolide-resistant MAC disease are macrolide monotherapy or macrolide treatment with inadequate companion medications. The treatment strategy associated with the highest rates of success for macrolide-resistant MAC lung disease includes the use of a multidrug regimen, including a parenteral aminoglycoside (streptomycin or amikacin), and surgical resection (“debulking”) of diseased lung.¹²³ The optimal drug regimen for treating macrolide-resistant strains is unknown but some experts recommend ethambutol, rifabutin, an injectable agent, and possibly another oral drug such as an 8-methoxyfluoroquinolone or clofazimine. One recent study suggests a modest favorable impact of moxifloxacin in this context.¹²⁸

Patients whose disease is predominantly localized to one lung and who can tolerate resectional surgery should be considered for surgery under the following conditions: (1) poor response to drug therapy, (2) development of macrolide-resistant MAC disease, or (3) presence of significant disease-related complications, such as hemoptysis. Outcomes of surgery have generally been favorable, with more than 80% culture conversion documented postoperatively.¹²⁹ Operative mortality has been low in most series except those that reported results on patients undergoing pneumonectomy. In a recent study reporting the outcomes of 134 patients undergoing video-assisted thoracoscopic surgery, there were no deaths, the complication rate was 7%, and cultures converted in 84% of the patients.¹³⁰ When possible, surgery should be performed by thoracic surgeons who have had extensive experience with resectional lung surgery for mycobacterial disease.¹³¹

Therapy of Disseminated MAC Disease. Successful treatment of disseminated MAC disease in persons with AIDS is based on treatment of both the mycobacterial and HIV infections. Clinicians must therefore be aware of the interactions between the antimycobacterial and antiretroviral medications. Current guidelines for the use of antimycobacterial drugs with HIV therapies can be found at www.cdc.gov/tb/default.htm.

Patients with disseminated MAC disease should be treated with clarithromycin at a dose of 1000 mg/day or 500 mg twice daily (or, as an alternative, azithromycin at a dose of 500 mg daily) and ethambutol at a dose of 15 mg/kg daily.¹³²⁻¹³⁴ Rifabutin, if added, should be used at a dose of 300 mg daily, with adjustments for interactions with antiretroviral drugs. As with macrolide-resistant MAC lung disease, patients with disseminated disease from macrolide-resistant strains are far less likely to be treated successfully.¹¹⁴ In the era preceding use of combination antiretroviral therapy for HIV, clofazimine was associated with excess mortality in HIV-infected patients with MAC bacteremia.¹³⁵ Whether those results apply to HIV-uninfected people or to the current setting in which combination antiretroviral therapy is used is unknown. In the absence of immune reconstitution, treatment of MAC in patients with AIDS should be considered lifelong, although MAC treatment may be stopped for patients who are asymptomatic, have completed 12 months or more of therapy, and have maintained a CD4⁺ T-cell count more than 100 cells/ μ L for at least 12 months.¹³⁶

Preventive therapy for disseminated MAC is recommended for all HIV-infected patients with fewer than 50 CD4⁺ T-cells/ μ L.¹³⁷ Based on efficacy and ease of use, azithromycin—given as 1200 mg once weekly—is the preferred agent.¹³⁸ Clarithromycin is also effective; however, it is considered an alternative agent because it must be given twice daily and the risk of breakthrough with macrolide-resistant strains is higher with daily clarithromycin than with weekly azithromycin. Rifabutin is also effective but should only be used when a macrolide cannot be tolerated. Primary MAC prophylaxis should be discontinued among adult and adolescent patients who have responded to antiretroviral therapy with an increase in CD4⁺ T-lymphocyte counts to more than 100 cells/ μ L for more than 3 months. Primary prophylaxis should be reintroduced if the CD4⁺ T-lymphocyte count drops below 50 to 100 cells/ μ L.

Therapy of MAC Lymphadenopathy. The treatment of choice for MAC lymphadenopathy, as well as for localized lymphadenopathy due to most NTM pathogens, is complete surgical resection of the involved lymph nodes.^{91,92,139,140}

When complete surgical resection is not possible due to nerve impingement or encasement by infected nodes, then chemotherapy with MAC treatment regimens similar to those for lung and disseminated disease are effective.¹⁴¹ Some studies have also suggested that a conservative, “wait and see” approach is also as effective as either surgery or antibiotic therapy for the majority of children with this process.¹⁴²⁻¹⁴⁴ Expert evaluation is advisable for optimal management of these children.

***Mycobacterium kansasii* Pulmonary Disease**

Mycobacterium kansasii is the second most common cause of NTM lung disease in the United States, but has also been reported in Europe, Asia, and Africa. Tap water is the major reservoir for *M. kansasii*.¹⁴⁵⁻¹⁴⁷ *Mycobacterium kansasii* lung disease most closely parallels the clinical course of *M. tuberculosis*, including radiographic abnormalities (Fig. 36-5; eFig. 36-2). While most patients with *M. kansasii* lung disease have upper lobe fibrocavitary findings, some patients have been reported with nodular/bronchiectatic radiographic abnormalities. In HIV-infected patients, *M. kansasii* can present with a wide spectrum of radiographic abnormalities (see eFig. 90-10).¹⁴⁸

Therapy of *Mycobacterium kansasii* Pulmonary Disease. The recommended regimen for treating pulmonary *M. kansasii* disease includes daily rifampin (600 mg/day), isoniazid (300 mg/day), and ethambutol (15 mg/kg/day) for a duration that includes 12 months of negative sputum cultures.⁹ Limited data suggest that therapy with rifampin, ethambutol, and clarithromycin for *M. kansasii* disease can also be successful,¹⁴⁹ including intermittent therapy.¹⁵⁰ The recommended treatment duration, as with MAC lung disease, is a duration that includes 12 months of sputum mycobacterial culture negativity.

Patients whose *M. kansasii* isolates are resistant to rifampin have been treated successfully with a regimen that consists of high-dose daily isoniazid (900 mg), high-dose ethambutol (25 mg/kg/day), and sulfamethoxazole (1 g three times per day) combined with several months of streptomycin or amikacin.¹⁵¹ The excellent in vitro activity

Figure 36-5 A 46-year-old male smoker with *Mycobacterium kansasii* lung disease. The patient presented with cough and weight loss. He was treated as a tuberculosis suspect initially but his sputum specimen was found to be culture positive for *M. kansasii*. **A**, Frontal chest radiograph shows a right upper lobe cavity. **B**, Frontal chest radiograph shows improvement in right upper lobe abnormalities after completing therapy.

of clarithromycin and moxifloxacin against *M. kansasii* suggests that multidrug regimens containing these agents and at least one other agent based on in vitro susceptibilities, such as ethambutol or sulfamethoxazole, are likely to be effective for treatment of a patient with rifampin-resistant *M. kansasii* disease.

Therapy of Disseminated *Mycobacterium kansasii* Disease.

The treatment regimen for disseminated disease, as usually observed in patients with AIDS, should be the same as for pulmonary disease.⁹ Because of the critically important role of rifamycins in the treatment of *M. kansasii* disease, it is important to construct *M. kansasii* and anti-retroviral treatment regimens that are compatible (see www.cdc.gov/tb/default.htm). An option for treating HIV-infected patients who receive an antiretroviral regimen not compatible with rifamycins is to substitute a macrolide or moxifloxacin for the rifamycin. There is no recommended prophylaxis regimen for disseminated *M. kansasii* disease.

Mycobacterium xenopi

Mycobacterium xenopi is a thermophile that survives in hot water systems and natural hot water reservoirs. Its survival in flowing water systems and resistance to common disinfectants enable *M. xenopi* to contaminate laboratory samples and medical devices such as bronchoscopes, thus causing health care–acquired disease, pseudoinfections, and laboratory contamination of specimens. Clusters of hospital isolates have been reported in the United States and Europe.¹⁵² Because of its environmental presence, the differentiation of true clinical infection from pseudoinfection may be difficult but is of paramount importance.

M. xenopi is rarely isolated in the United States; however, it is the second most common cause of NTM lung disease in Canada, the United Kingdom, and some parts of Europe.¹⁵³ Pulmonary infections are most common, but extrapulmonary and disseminated infections have been reported. Impaired immunity, either local (preexisting pulmonary disease) or systemic (HIV, immunosuppressive medications), appear to predispose to *M. xenopi* infections. Radiographic findings with *M. xenopi* pulmonary disease are variable but most often include upper lobe cavitory abnormalities similar to tuberculosis.

In a report of therapy for *M. xenopi* infections, overall mortality was high—and mostly unrelated to *M. xenopi* disease—and the response to chemotherapy was not correlated with in vitro susceptibility results.¹⁵⁴ In another report from Europe, *M. xenopi* isolates demonstrated favorable in vitro minimal inhibitory concentrations to isoniazid, rifampin, and ethambutol.¹⁵³ Even with variable treatment regimens, antimicrobial treatment cured 58% of patients who met American Thoracic Society criteria for *M. xenopi* lung disease.¹⁵³ In that study, there was no correlation between failure or treatment relapse and in vitro susceptibility results. In recent published treatment results, a regimen of clarithromycin, rifampin, and ethambutol was compared to ciprofloxacin, rifampin, and ethambutol; treatment success, failure, or relapse did not differ between the two groups.¹⁵⁵ All-cause mortality was again relatively high, and somewhat higher in the ciprofloxacin, rifampin, ethambutol arm. A combination of ethambutol and rifampin with either clarithromycin or moxifloxacin was bactericidal in vitro and ex vivo.¹⁵⁶ Amikacin containing regimens were the most effective in a nude mouse model. Overall, the optimal pharmacologic management has yet to be determined; however, a regimen consisting of clarithromycin (or moxifloxacin), rifampin, and ethambutol, administered for a duration of therapy that includes 12 months of sputum culture negativity, is commonly used. Addition of amikacin may be advisable in patients with more extensive disease. The unusually high overall mortality with this infection is difficult to explain, but may be a reflection of the comorbidities of the patients with *M. xenopi* disease.

Mycobacterium malmoense

Mycobacterium malmoense is considered the second most serious pathogen after MAC in Northern Europe. In patients in Europe, 70% to 80% of *M. malmoense* isolates have been considered clinically relevant, while clinical isolates in the United States are deemed clinically significant less frequently.¹⁵⁷ Patients with *M. malmoense* lung disease frequently have preexisting obstructive lung disease, and *M. malmoense* lung disease often presents in a manner similar to other cavitory NTM lung disease pathogens. Overall, the in vivo response to antimicrobials does not correlate with in vitro susceptibility to antimicrobial agents. In a recent

report, clarithromycin, rifampin, and ethambutol were compared with a regimen consisting of ciprofloxacin, rifampin, and ethambutol.¹⁵⁵ Although a more favorable response to therapy was obtained with the macrolide-containing regimen, overall mortality did not differ between the two regimens, and the optimal pharmacologic management of *M. malmoense* has yet to be determined.^{155,158} Currently, a suggested regimen for *M. malmoense* consists of rifampin, ethambutol, and clarithromycin with or without isoniazid for a duration to include 12 months of sputum culture negativity.¹⁵⁷

Mycobacterium simiae

Recovery of *M. simiae* from clinical specimens has been reported in three geographic regions, Israel, Cuba, and the Southwestern United States, including Texas, Arizona, and New Mexico. The organism is most often isolated as a single positive specimen that is smear negative and not associated with clinical disease. For several clusters of isolates, organisms were also recovered from the local tap water, suggesting it as the likely source.^{159,160} A large pseudo-outbreak of *M. simiae* isolates from an urban hospital in Texas has been reported.¹⁶¹ The source for most of the recovered organisms was a hot water holding area. In most published series, the majority of *M. simiae* isolates have been judged to be not clinically significant.^{161,162} In a recent publication, the authors noted, "The available diagnostic criteria are inadequate for the selection of patients for whom drug treatment for true *M. simiae* infection would be beneficial."¹⁶² When *M. simiae* is a significant pathogen, it is most often associated with pulmonary disease or, in immunocompromised hosts, disseminated disease.

As with other NTM, there is no established correlation between in vitro susceptibility of the organism and in vivo clinical response to antimicrobial agents, nor is there an established, predictably reliable treatment regimen for *M. simiae* disease. In a study from Israel,¹⁶³ there were no recurrences reported in 102 patients with pulmonary *M. simiae* disease after treatment with rifampin, ethambutol, and clarithromycin given daily for at least 12 months of negative sputum cultures. These results are in sharp contrast to the experience of many experts in the United States who find *M. simiae* to be among the most difficult to treat pulmonary NTM pathogens. Some experts suggest using macrolide-based regimens similar to those used for MAC; in addition, other agents such as fluoroquinolones, sulfamethoxazole, and linezolid may have some activity against this organism.

Mycobacterium szulgai

Mycobacterium szulgai is characterized primarily by cavitary lung disease in patients with underlying chronic lung disease. As with other NTM pathogens, it can also be associated with nodular/bronchiectatic disease. Most respiratory isolates of *M. szulgai* are associated with significant lung disease: 11 of 15 patients (73%) in The Netherlands who grew *M. szulgai* from their sputum met current American Thoracic Society criteria for disease.¹⁶⁴ In vitro susceptibilities demonstrate susceptibility to rifampin, isoniazid, ethambutol, and clarithromycin. A recent study suggested that regimens containing a rifamycin, ethambutol, and clarithromycin with or without a fluoroquinolone for approxi-

mately 12 months have almost 100% treatment success.¹⁶⁴ Unlike many other NTM pathogens, the in vitro susceptibilities for *M. szulgai* appear to predict favorable treatment response.

RAPIDLY GROWING MYCOBACTERIA

RGM are distinguished by growth in subculture in less than 7 days and comprise more than 80 distinct species, at least 18 of which have been associated with lung disease (see Table 36-1). Because many RGM are not pathogenic in humans, it is important to subclassify organisms within this group to the species level since this affects both treatment and prognosis. Although RGM can produce pulmonary disease, they have a propensity to produce skin and soft tissue infections.

Mycobacterium abscessus

Mycobacterium abscessus is the third most common NTM infection in the United States and causes at least 80% of pulmonary infections due to RGM.⁵⁷ By genome sequencing, *M. abscessus* can be divided into additional subspecies, *Mycobacterium bolletii* and *Mycobacterium massiliense*.¹⁶⁵ Most patients with pulmonary disease due to *M. abscessus* are nonsmoking white women older than 60 years who have no predisposing conditions. The usual clinical presentation is similar to that of other NTM pulmonary infections and includes cough and easy fatigability. For most patients without predisposing conditions, the disease is slowly progressive; however, more fulminant, rapidly progressive disease has been seen in patients with gastroesophageal disorders and CF. The chest radiograph usually shows multilobar, patchy, reticulonodular or mixed reticulonodular alveolar opacities⁵⁷ (Fig. 36-6). HRCT findings include the presence of cylindrical bronchiectasis with multiple small nodules, similar to the findings in MAC lung disease.^{57,112,166} Cavitation has been reported in 10% to 40% of patients. In one report, 20% of patients died as a consequence of *M. abscessus*.⁵⁷

Therapy of *Mycobacterium abscessus* Pulmonary Disease.

M. abscessus is typically resistant in vitro to most of the medications used to treat tuberculosis, and has demonstrated in vitro activity to only a few antimicrobial agents. Cure can be elusive for many patients with *M. abscessus* lung disease with medical therapy. Among 65 patients from South Korea with pulmonary *M. abscessus* disease who were treated with a standardized regimen including 4 weeks of intravenous amikacin and cefoxitin along with oral ciprofloxacin, clarithromycin, and doxycycline for a total duration of 24 months, sputum was converted and negative cultures were maintained for more than 12 months in only 58% of patients.^{166a} In a U.S. study of 107 patients treated with individualized therapy that included intravenous imipenem (or cefoxitin) and amikacin along with various oral and inhaled combinations of therapy,¹⁶⁷ only 48% of cases converted and maintained negative cultures for at least 12 months. Current guidelines recommend that therapy usually consists of 2 to 4 months of intravenous agents such as imipenem or cefoxitin plus amikacin given daily or three times weekly.⁹ Any oral agents that have demonstrated in vitro activity should be included in the treatment

Figure 36-6 A 68-year-old nonsmoking woman with several-year history of cough, fatigue, and weight loss. Her sputum cultures were consistently positive for *M. abscessus*. **A**, Frontal chest radiograph shows middle and lower lung zone nodular opacities and bronchiectasis. **B**, Axial chest CT shows right middle lobe atelectasis and bronchiectasis with bilateral lower lobe bronchiectasis and nodular opacities. Note the left lower lobe air space opacity in this patient with severe reflux and probable chronic aspiration.

regimen. While macrolides have traditionally been used in this role, recent studies have questioned the importance of macrolides in the treatment of *M. abscessus* subspecies *abscessus* because the organism contains the *erythromycin ribosomal methylase (erm[41])* gene.¹⁶⁸ When the organism is incubated in the presence of clarithromycin, the gene is induced and the organism rapidly acquires macrolide resistance. In contrast, *M. massiliense* has a nonfunctional copy of the gene so macrolide resistance is not induced in the presence of clarithromycin. In a study from South Korea, patients infected with *M. massiliense* were more likely to improve clinically, radiographically, and bacteriologically than those with *M. abscessus*: in 88% of those with *M. massiliense*, sputum cultures converted to negative versus 25% with *M. abscessus*.¹⁶⁹ Limited data suggest that azithromycin may be more effective than clarithromycin against *M. abscessus*.^{170,171}

Species identification discriminating between *M. abscessus* and *M. massiliense* informs clinicians about the presence of an active *erm* gene and presumptive antibiotic choices but is frequently not available from reference laboratories. However, the presence of an active *erm* gene can be ascertained in most mycobacteriology laboratories in a relatively short time and is the critical information needed by the clinician to guide antibiotic therapy for isolates initially identified as *M. abscessus*.

Linezolid, an oxazolidinone, is active against some strains of *M. abscessus*, but is frequently associated with significant hematologic toxicity and peripheral neuropathy.^{171,172} Tigecycline has in vitro activity against *M. abscessus*, but is available only as an intravenous preparation and is associated with significant nausea and vomiting.^{172a} Clofazimine has in vitro activity against *M. abscessus* and synergistic activity with amikacin¹⁷³; however, its role in the management of these patients remains to be defined.

Once a patient has demonstrated a clinical response to therapy, there are several possible choices for continued treatment: (1) stop therapy after 2 to 4 months and follow the patient for signs of progression of disease and, if present, periodically reinstitute treatment; (2) stop the aminoglycoside and continue the cefoxitin or imipenem for a longer period along with an oral agent; and (3) continue an oral agent and institute inhaled amikacin. Unfortunately, none of these choices is based on evidence, so treatment decisions need to be individualized and often some form of therapy will be required periodically on a lifelong basis.

A combination of surgical resection and chemotherapy may increase the chance of cure in patients who have focal lung disease and who can tolerate resection. Patients should be treated with an initial period of antimicrobial drug therapy prior to surgery to lessen the bacillary load.⁹ In three studies, patients who underwent surgical resection in addition to antimicrobial chemotherapy had improved microbiologic outcomes compared with those who received chemotherapy alone.^{57,167,174} As with MAC lung disease, surgery should be performed by thoracic surgeons experienced in performing this type of surgery.¹³¹

Mycobacterium abscessus lung infection has been considered a contraindication for lung transplantation in patients with CF; however, recent reports suggest that lung transplantation for patients with CF can be accomplished with success rates comparable to those of noninfected patients.^{175,176}

Therapy of *Mycobacterium abscessus* Skin, Soft Tissue, and Bone Infections. Serious infections should be treated with a regimen similar to that used for pulmonary disease. Skin and soft tissue infections should be treated for a minimum of 4 months and bone infections for 6 months. Surgery is generally indicated for extensive disease, for abscesses, or when drug therapy is difficult.⁹ Foreign bodies such as prosthetic joints, percutaneous catheters, and breast implants should be removed, and the patient treated with a prolonged antimicrobial treatment regimen.

Mycobacterium chelonae

M. chelonae is more likely to produce skin, soft tissue, and bone infections than pulmonary disease. Keratitis due to *M.*

chelonae has been associated with contact lenses and with ocular surgery such as laser-assisted in situ keratomileusis (LASIK).^{177,178} Disseminated disease has been reported in immunocompromised patients and usually presents with characteristic cutaneous lesions.¹⁷⁹ The clinical and radiographic presentation of *M. chelonae* pulmonary disease is similar to that of other RGM.

Isolates of *M. chelonae* are usually susceptible to tobramycin, the macrolides, linezolid, and imipenem.^{99,180,181} The *M. chelonae* genome does not include an active *erm* gene, indicating that in vitro susceptibility to macrolides has value in predicting in vivo responses to therapy.¹⁶⁸ Other active drugs may include amikacin, clofazimine, doxycycline, and the fluoroquinolones. *M. chelonae* isolates are uniformly resistant to ceftioxin. Treatment of *M. chelonae* infections should be based on in vitro susceptibility results. Administration of clarithromycin 500 mg twice daily for 6 months was reported to have a high cure rate in patients with cutaneous lesions associated with disseminated disease.¹⁸² The one patient who relapsed did so with a macrolide-resistant strain. Patients have also responded to linezolid with or without clarithromycin.^{183,184} Patients with serious skin, soft tissue, and bone infections should be treated similarly to those with *M. abscessus* disease. For corneal infections, both topical and oral agents are often used, and many patients may require corneal transplants for recovery of vision or for cure.

Mycobacterium fortuitum

M. fortuitum is responsible for up to 15% of RGM cases in the United States but is a relatively uncommon cause of lung disease except in patients with disorders associated with chronic aspiration.⁵⁷ Among 26 patients in the Republic of Korea with two or more positive cultures for *M. fortuitum*, only one was treated and none of the 25 untreated patients showed progression during a median follow up of 12.5 months.¹⁸⁵ The clinical and radiographic presentation of patients with pulmonary disease is similar to that of other RGM. Application of contemporary diagnostic guidelines must be used with caution and even with some skepticism when evaluating patients with *M. fortuitum* respiratory isolates. Skin, soft tissue, and bone infections are more common than pulmonary disease. Both sporadic and clustered outbreaks of furunculosis due to *M. fortuitum* (and other RGM) have been reported after exposure to contaminated water during pedicures.¹⁸⁶⁻¹⁸⁸

In contrast to *M. abscessus*, *M. fortuitum* demonstrates broader in vitro susceptibility to both oral and intravenous antimicrobial drugs, including the newer macrolides, the fluoroquinolones, doxycycline, minocycline, the sulfonamides, and two intravenous drugs, imipenem and ceftioxin.⁹ Although most isolates of *M. fortuitum* are susceptible in vitro to the macrolides, these drugs should be used with caution because of the presence of an inducible *erm* gene.¹⁸⁹

Mycobacterium fortuitum lung disease should be treated with at least two drugs to which in vitro susceptibility has been demonstrated.⁹ As with other NTM lung infections, treatment should be continued for at least 12 months of negative sputum cultures. Skin, soft tissue, and bone infections should be treated similarly to *M. abscessus* infections, although oral agents are more often effective.

THERAPEUTIC DRUG MONITORING

The role of therapeutic drug monitoring in management of NTM lung disease remains controversial. Low serum concentrations of clarithromycin have been reported when the drug is given in combination with rifampin.¹⁹⁰⁻¹⁹² A recent study examined the pharmacokinetic and pharmacodynamic relationships in 481 patients with MAC lung disease.¹⁹¹ This study reported that peak serum concentrations were below the target range for ethambutol in 48% of patients, clarithromycin in 56%, and azithromycin in 35%. Concurrent administration of rifampin reduced the mean serum concentration of clarithromycin by 68% and that of azithromycin by 23%. Pharmacodynamic indices (the desired ratio of serum concentrations to the minimal inhibitory concentration of the drug) were seldom met for rifampicin, clarithromycin, amikacin, and moxifloxacin. This study did not examine a possible correlation between clinical outcome and the poor pharmacodynamics indices. A study from South Korea reported that peak plasma concentrations of clarithromycin were lower in MAC patients who received daily or intermittent therapy when combined with rifampicin compared with *M. abscessus* patients who received clarithromycin without rifampicin.¹⁹² In this study, treatment outcomes were not associated with plasma drug concentrations; however, no attempt was made to increase the dosage in patients with low concentrations to determine whether outcomes would have improved. Thus, while the role of therapeutic drug monitoring remains to be defined in uncomplicated cases of NTM infection, it should be considered in patients who are failing therapy, have end-stage renal disease, or who are taking medications that are known to involve interactions with other drugs.

HYPERSENSITIVITY PNEUMONITIS-LIKE NONTUBERCULOUS MYCOBACTERIA PULMONARY DISEASE

Most reports describing the development of a typical pattern of hypersensitivity pneumonitis-like lung disease have been in patients with hot tub exposure, although similar clinical presentations have been associated with other indoor standing water sources and exposures.^{40,193,194} In one case report, hypersensitivity-like lung disease was observed in association with an indoor shower.⁴⁰ Some investigators have used the phrase "hot tub lung" to describe the presentation associated with standing water sources. In the cases of exposure to hot tubs, MAC has been the mycobacterial organism isolated from sputum, bronchoalveolar lavage, tissue, and hot tub water. Furthermore, when assessed by genotyping methods, MAC isolates from both the hot tub water and the lung specimens have demonstrated identical patterns. Controversy still exists, however, as to whether hot tub lung is an infectious process, inflammatory process, or a combination of the two.

Patients with hypersensitivity pneumonitis-like lung disease tend to be young and without preexisting lung disease. The clinical presentation can vary from mild respiratory symptoms to respiratory failure requiring mechanical ventilatory support.¹⁹⁵ Key elements to the diagnosis of MAC hypersensitivity-like lung disease include a compatible clinical history (subacute onset of respiratory symptoms,

hot tub exposure), characteristic radiographic findings, and MAC isolates in sputum, bronchoalveolar lavage, tissue, and hot tub water (with compatible histopathology when available).

The prognosis is generally excellent and independent of severity on presentation.¹⁹³ The greatest benefit is gained by simply removing the patient from further antigen exposure. In the case of hot tub lung, removal from antigen exposure generally involves drainage of hot tub water and complete avoidance of hot tub use. Whether continued exposure to ambient environmental MAC organisms can propagate the hypersensitivity pulmonary reaction is uncertain. For selected patients with hypersensitivity pneumonitis-like lung disease, use of systemic corticosteroids may be beneficial and promote recovery of pulmonary symptoms, gas exchange abnormalities, and radiographic abnormalities. Likewise, antimycobacterial therapy, with the same medications as for standard pulmonary MAC lung disease, may be required in some patients but for shorter durations of therapy, usually 3 to 6 months. Most patients can be expected to have nearly complete resolution of respiratory symptoms as well as of pulmonary function and radiographic abnormalities.

HEALTH CARE–ASSOCIATED NONTUBERCULOUS MYCOBACTERIA DISEASE AND PREVENTION OF NTM INFECTIONS

NTM are ubiquitous in the environment, so complete avoidance is difficult if not impossible. Compared with *M. tuberculosis*, NTM have low virulence for humans, so NTM disease may be more a problem with host susceptibility than with organism contact. With some notable exceptions discussed previously, the specific susceptibility of an individual patient to NTM infection may be impossible to determine with current knowledge of immunity and pathogenesis; accordingly, disease prevention remains problematic. It also remains unclear whether patients with known heightened susceptibility to NTM infection should be advised to avoid known environmental sources of NTM. For example, it is unclear whether susceptible patients should be advised not to take showers, which are known to be associated with aerosolized NTM.³⁹

Progress has been made in prevention of nosocomial NTM infections. Transmission of NTM in health care settings has most frequently been linked to tap (municipal) water exposure.⁹⁰ While various NTM species (including MAC, *M. kansasii*, *M. xenopi*, and *M. simiae*) have been isolated from municipal water supplies, *M. fortuitum* and *M. abscessus* have most often been implicated in health care–associated NTM disease. Even with use of potent disinfectants, including organomercurials, chlorine, bromine, 2% formaldehyde, and glutaraldehyde, NTM may persist on equipment or devices after tap water exposure. A large outbreak of *M. massiliense* in Brazil involved a single clone that was tolerant to 2% glutaraldehyde.¹⁹⁶ The inability to eliminate these organisms underscores the importance of avoidance of tap water for preventing health care–associated

NTM diseases, such as those following median sternotomy, plastic surgery procedures, liposuction, LASIK, dialysis, and the implantation of long-term central intravenous catheters, tympanostomy tubes, and prosthetic devices such as heart valves, knee and hip joints, lens implants, and metal rod bone stabilizers.⁹ Pseudo-outbreaks have involved bronchoscopes contaminated with *M. abscessus* and *Mycobacterium immunogenum*. Documented outbreaks of hygiene-associated *M. fortuitum* and *Mycobacterium magritense* furunculosis in association with use of contaminated whirlpool footbaths have been described in nail salons.^{188,197}

As a result of the increased understanding of environmental NTM reservoirs and reports linking the use of tap water to health care–associated NTM infections, it is recommended that tap water not be used in preparation of surgical procedures, prosthetics, and intravascular catheters; not be used in cleaning of fiberoptic endoscopes; and not be used to rinse the mouth out before collecting expectorated sputum samples. Moreover, recognition that alternative medicines or unapproved substances for injection may also be at risk of contamination by NTM warrants caution against use of these products as well.

Key Points

- Nontuberculous mycobacteria (NTM) comprise more than 160 different species that are ubiquitous in the environment. Members of the *Mycobacterium avium* complex (MAC) are the most common causes of NTM lung disease.
- Infection develops after exposure to NTM in the environment; person-to-person transmission is exceptionally uncommon.
- Although there are fewer species of slowly growing NTM than rapidly growing species, the slow growers are more common causes of lung disease.
- Epidemiologic studies suggest that the prevalence of NTM infections is increasing in some areas of the world, including the United States.
- Risk factors for pulmonary NTM disease include underlying chronic lung diseases such as bronchiectasis, chronic obstructive pulmonary diseases, cystic fibrosis, alpha₁-antitrypsin deficiency, and prior tuberculosis.
- Diagnosis of pulmonary NTM infection requires that the patient meet certain clinical, radiographic, and microbiologic criteria.
- The recommended treatment for MAC pulmonary disease is a macrolide, plus ethambutol and a rifamycin, with or without an aminoglycoside, administered for at least 12 months of negative sputum cultures.
- Because of the critical importance of macrolides for the successful treatment of MAC, macrolide use should be avoided in patients who may require treatment for MAC in the future.
- The recommended treatment for *Mycobacterium kansasii* pulmonary disease is isoniazid (or macrolide), rifamycin, and ethambutol administered for at least 12 months of negative sputum cultures.
- Treatment of rapidly growing mycobacterial infections should be based on the results of in vitro drug susceptibility testing, but the clinical outcome varies significantly depending on the causative species.

more than a year of treatment, and lifelong therapy may be required in the setting of irreversible immunodeficiency.

INTRODUCTION

Geographically restricted (or endemic) mycoses include histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidioidomycosis, sporotrichosis, and penicilliosis. Of these, histoplasmosis, coccidioidomycosis, blastomycosis, and paracoccidioidomycosis have the most defined geographic distributions in the Americas (Fig. 37-1). These are considered *dimorphic* pathogens because they grow as mycelium in nature and undergo morphogenesis into yeasts or spherules upon acquisition by humans. These phases can be reproduced in the laboratory by cultivation at low (approximately 25°C) or high (37°C) temperatures, respectively. Hence, these fungi are termed “thermally dimorphic.” Acquisition is typically via inhalation of spores or mycelial fragments, although sporotrichosis is most commonly initiated by skin puncture. The mycelia produce spores that are situated external to the fungus and are easily aerosolized when disturbed; these spores (e.g., conidia, macroconidia, microconidia or arthroconidia) are thought to be the infectious agents and inhalation of these spores lead to pulmonary disease. The severity of clinical illness is linked to the quantity of the inoculum as well as the susceptibility of the individual. Defects in cellular immunity are associated with more severe disease. Latent infections can reactivate in individuals whose immune responses have been compromised, such as by steroids, inhibition of tumor necrosis factor, chemotherapy, or *human immunodeficiency virus* (HIV). The geographically restricted mycoses are often overlooked as etiologies of infectious diseases such as community-acquired pneumonia; for example, it is not uncommon for these patients to receive several antibacterial antibiotics for suspected anaerobic infections before histoplasmosis is diagnosed.¹ This is due to clinical disease manifesting in geographic regions where the fungi are uncommon or absent, leading to delays in recognition and treatment. Treatment of these diseases requires several months to

HISTOPLASMA

HISTORY AND EPIDEMIOLOGY

Histoplasma capsulatum is a dimorphic fungus primarily acquired via respiratory exposure that is responsible for approximately 500,000 infections annually in the United States, which makes it the most prevalent cause of fungal pulmonary disease.² Similarly, these calculations also indicate that nearly 50 million North American residents are latently infected with the fungus. The fungus is endemic worldwide, although there are areas with a high incidence of disease. The Ohio and Mississippi River Valleys in the United States are a highly endemic region and skin testing has shown that up to 90% of adults in these regions have been exposed to the fungus.^{3,4} High endemicity areas are also present in Latin America, particularly within Brazil, Venezuela, Ecuador, Paraguay, Uruguay, and Argentina. For example, the prevalence in Midwestern and Southeastern portions of Brazil has been reported as approximately 63% and 93%, respectively.⁵

The most recent data on rates of clinically significant disease in the United States are from an extraction of data from the Nationwide Inpatient Sample, a database of diagnostic codes of diseases, for the year 2002.⁶ This methodology likely underestimates the incidence of hospitalizations for histoplasmosis or other endemic mycoses due to diagnostic difficulties and incomplete coding. Nevertheless, in 2002, there were 3259 adults (60% male, 40% female) and 111 children (42% male, 58% female) hospitalized with histoplasmosis. The majority of patients were not known to have an underlying immunodeficiency, with only 14% of adults having an immune defect while 32% of children were considered immunocompromised. In-hospital mortality rates were 8% and 5% for adults and children, respectively. Hence, there are approximately 270 deaths due to *H. capsulatum* annually in the United States. For comparison,

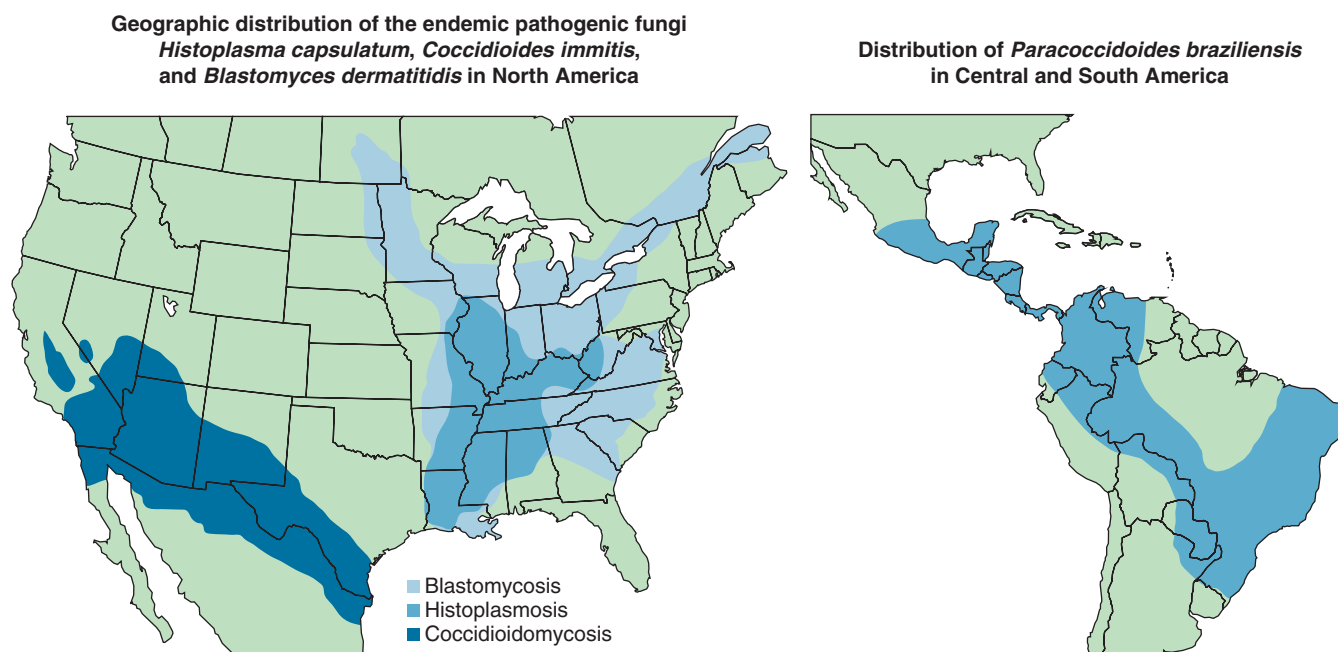

Figure 37-1 Geographic distribution of the endemic fungi in the Americas. In North America, the regions where histoplasmosis, coccidioidomycosis, and blastomycosis are endemic are shown. In South America, the region where paracoccidioidomycosis is found is shown. Note that histoplasmosis and coccidioidomycosis can also be found in Central and South America; however, blastomycosis and paracoccidioidomycosis appear to be limited to either North or South America, respectively.

in 2009 (the most current complete U.S. death statistics), 529 deaths were due to tuberculosis (405 due to respiratory tuberculosis), 99 due to meningococcal infection, 26 due to salmonellosis, and 3 due to malaria.⁷

The genus *Histoplasma* was designated in 1906 by Samuel Darling who described the fungus in the lungs, liver, spleen, and lymph nodes of a carpenter from Martinique working on the Panama canal.⁸ Darling incorrectly characterized the 1- to 4- μ m intracellular ovoid yeast as protozoa, similar to *Leishmania* sp. Subsequent to the identification of *H. capsulatum* by Darling, several varieties of *Histoplasma* were identified, with distinct geographic or host niches. More recently, analysis of sequence diversity of four protein-coding genes of *H. capsulatum* revealed that the different varieties of *Histoplasma* are not phylogenetically distinct and that *H. capsulatum* comprises seven phylogenetic species, which radiated rapidly from a single ancestor between 3 million and 13 million years ago.⁹

PATHOGENESIS

H. capsulatum exists in either a filamentous or yeast form, depending mainly on temperature and nutritional conditions.¹⁰ In the environment and at ambient temperatures, *H. capsulatum* is mycelial. This saprophytic mold grows particularly well in soils enriched with organic nitrogen sources, such as areas contaminated with bird or bat droppings. Hyphal elements are 1.25 to 2 μ m in diameter and produce two types of spores called conidia: thick walled macroconidia (8- to 15- μ m diameter) and microconidia (2- to 5- μ m diameter). Both conidial forms are produced singly at the tips of narrow, short conidiophores that branch at right angles to vegetative hyphae. The microconidia are the purported infectious particle, in that their size is

most effective for aerosolization and subsequent inhalation and deposition into distal lung structures. Environmental disturbances, especially construction or tree removal, are highly associated with aerosolization of *H. capsulatum*. At 37°C or in human tissues, the yeast form is the predominant morphology. Yeast cells have thin walls and are oval with diameters from 2 to 5 μ m. The cells reproduce by polar budding with a narrow bridge between the mother and daughter cells. Rarely, it is possible to find both yeast and mycelial forms in lung tissues¹¹ as well as on endovascular devices.¹²

Histoplasmosis is initiated by inhalation and deposition of microconidia within alveoli. This event is followed by conversion of microconidia to the yeast form,¹³ which begins within several hours to a few days.¹⁴ Morphogenesis is initiated by the shift in temperature and availability of nutrients. Notably, despite the species name, the cells lack a capsule. During primary infection, the yeast cells are phagocytosed into the endosomal compartment of phagocytes and these infected host cells then migrate to hilar and mediastinal lymph nodes and subsequently disseminate hematogenously, distributing the fungus into diverse tissues. In fact, autopsy studies have found that approximately 70% of individuals with history of histoplasmosis have splenic granulomas.¹⁵ The incubation period for disease manifestations is typically 8 to 17 days, although heavy exposure may result in disease in as little as 3 days.¹⁶

It is understood that effective control of histoplasmosis requires activation of cellular immunity in concert with innate responses, because the absence of intact immunity leads to disseminated, progressive disease.¹⁷ Additionally, impairment of cellular immunity in latently infected individuals can result in the reactivation of previously controlled foci of infection. Although significantly less common

in the current era of effective antiretroviral medications, individuals with *acquired immunodeficiency syndrome* (AIDS) are at high risk for reactivation disease (see Chapter 90). Histoplasmosis also reactivates in patients receiving anti-cytokine therapies.¹⁸ Reactivation disease has also been documented in liver transplant recipients with disease originating from latent infections in the transplanted organs,¹⁹ and disease is associated with a high incidence of graft loss and mortality.

Neutrophils are considered primary responders to *H. capsulatum* in the lung²⁰; however, the majority of yeast are found within immature dendritic cells on the first day after experimental pulmonary infection of mice. In the same murine model, neutrophils predominate for several days thereafter. Human neutrophils effectively inhibit the fungus, and azurophilic granules are responsible for this fungistatic effect.²¹ Resident and inflammatory macrophages contain significant numbers of yeast cells by 3 days after experimental infection and yeast cells are primarily in inflammatory macrophages by the end of the first week. Although experimental systems have shown that murine dendritic cells and macrophages fail to control replication and facilitate dissemination, human dendritic cells and macrophages, especially activated macrophages, can efficiently kill *H. capsulatum* yeast cells.²² Moreover, human dendritic cells can inhibit conidial germination,²³ which can modify subsequent disease progression by presenting fungal antigen to CD8⁺ T cells. Several experimental studies have suggested that CD8⁺ T cells are instrumental in initial clearance of *H. capsulatum* yeast cells, whereas CD 4⁺ T cells are required for survival.¹⁷ The role of antibody in histoplasmosis is controversial, although monoclonal antibodies have been shown to modify the pathogenesis of disease.^{24,25} Consistent with a key role for B cells in histoplasmosis is the finding that depletion of B cells significantly enhances the severity of disease.²⁶

Among the many innate elements engaged in augmentation of protective immunity to *H. capsulatum* are several cytokines, including interleukin-12, *tumor necrosis factor* (TNF)- α , granulocyte macrophage colony-stimulating factor,²⁷ and interferon- γ .¹⁷ The ability of lymphocytes and phagocytes to produce these cytokines constitutes a major effector mechanism of host resistance. The critical role of TNF is underscored, as described earlier, by the association of inhibition of this cytokine and the development of severe histoplasmosis. The lack of TNF is thought to diminish control of intracellular growth of the fungi and leads to dysregulation of granulomas containing *H. capsulatum* yeast cells and/or an inability to form new granulomas. In the setting of intact immunity, granuloma formation can be caseating and indistinguishable from that caused by *Mycobacterium tuberculosis*. As in tuberculosis, healing of granulomas can also result in calcification of lesions, especially in lymph nodes and in the liver and spleen.¹⁵

CLINICAL MANIFESTATIONS

The severity of histoplasmosis is closely linked to the number of spores inhaled, the virulence of the infecting strain, and the immunologic status of the exposed individual.²⁸ The most common presentation is pneumonia, although the disease may involve virtually any tissue and can manifest as a fulminant life-threatening disseminated sepsis. Low

inoculum infection results in development of self-limiting disease in 1% of individuals, while 99% have subclinical infection.²⁹ In contrast, high inoculum infection leads to symptomatic disease in 50% to 100% of exposures.³⁰ Therefore, infection usually results in a mild, often asymptomatic respiratory illness, but may progress to life-threatening systemic disease, particularly in immunocompromised individuals. In the setting of HIV infection, disseminated histoplasmosis has been considered an AIDS-defining illness, although the prevalence of histoplasmosis in individuals with HIV has diminished with currently available antiretroviral regimens.

Acute Histoplasmosis

As noted, the most common outcome after exposure to *H. capsulatum* is an asymptomatic infection. However, 1 to 3 weeks after acquisition, acute disease can manifest.³¹ Symptomatic histoplasmosis typically presents as a flulike illness with the rapid onset of fever, chills, headache, myalgia, nonproductive cough, and chest pain. Chest radiographs are generally unrevealing, although mediastinal lymphadenopathy with (Fig. 37-2A) or without opacities may be present. However, approximately 1 in 2,000 adults will develop acute progressive pneumonia,³² associated with a heavy exposure to *H. capsulatum*.³³ In acute disease, approximately 10% of patients have rheumatologic symptoms, such as arthritis or severe arthralgia accompanied by erythema nodosum.³⁴ Additionally, pericarditis can develop in approximately 10% of patients with acute disease,³⁵ although pericarditis is typically a late manifestation after the resolution of pulmonary symptoms. Uncommonly, lymph node enlargement may cause compression of mediastinal structures.³⁶ Although resolution is typical, surgical decompression may be required to alleviate esophageal compression or endovascular stenting may be needed to prevent superior vena caval occlusion. Mediastinal fibrosis (eFig. 37-1) is a rare postinfectious complication that is perceived to be due to an abnormal inflammatory response to residual *H. capsulatum* antigens; this disease is more common in individuals with an HLA-A2 allele.³⁷ Steroids or antifungal agents are not useful in mediastinal fibrosis and surgery has not proven to be particularly effective, although endovascular stenting has been reported to alleviate vascular complications.³⁸ The majority of patients with acute pulmonary histoplasmosis recover over several weeks without sequelae, although occasional patients complain of fatigue persisting for months. Subsequent radiographs may appear normal or demonstrate a single calcified (eFig. 37-2) or noncalcified nodule or “coin” lesion, or a miliary pattern of calcified granulomas indistinguishable from that found in certain tuberculosis patients¹⁶ (Fig. 37-3). The miliary appearance is more common in disease associated with a high inoculum exposure. Although it is well recognized that pulmonary coin lesions can be sequelae of histoplasmosis, surgical resections continue due to suspicion of neoplasm.³⁹ Positron emission tomography may be of limited value, because they can display enhanced uptake in histoplasmosis nodules.⁴⁰

Disseminated Histoplasmosis

H. capsulatum can rapidly spread throughout an infected host because the fungus is transported intracellularly by

Figure 37-2 Acute histoplasmosis. **A**, Frontal chest radiograph in a patient with acute histoplasmosis shows numerous bilateral small nodules (arrowheads) and right paratracheal lymphadenopathy (arrow). **B**, Photomicrograph of bone marrow biopsy specimen shows abundant small yeast in macrophages. There were no well-formed granulomas. (Wright stain; original magnification $\times 450$.) (**A**, Courtesy Michael Gotway, MD.)

phagocytes from the lungs via the hilar lymphatics into the systemic circulation.²⁰ Although this process is controlled in most infected patients, histoplasmosis becomes systemic in approximately 0.05% of individuals after exposure.³² Histoplasmosis (eFig. 37-3) most commonly disseminates in individuals with preexisting immunosuppression largely due to malignancy, corticosteroid use, or AIDS. Clinical manifestations of disseminated histoplasmosis can vary from indolent to fulminant. Patients typically present with fever, weight loss, and respiratory symptoms. Patients often have hepatomegaly and/or splenomegaly. Cutaneous and mucous membrane lesions are not uncommon, and patients should be considered to have disseminated disease if *H. capsulatum* is isolated from these sites. Patients with acute disease often have anemia, thrombocytopenia, leukopenia, and abnormal liver function tests as well as coagulopathies.⁴¹ The majority of patients have diffuse pulmonary opacities, but chest radiographs can be unrevealing in approximately 30% of patients.⁴² The central nervous system is involved in 10% to 20% of cases.⁴³ Endovascular

Figure 37-3 Multiple calcified pulmonary granulomas due to histoplasmosis. Frontal chest radiograph shows numerous small calcified nodules (arrows) bilaterally due to previous disseminated histoplasmosis. (Courtesy Michael Gotway, MD.)

disease is not common but, interestingly, mycelial as well as yeast forms can be present in the vegetation.¹² Adrenal dysfunction may develop in approximately 50% of patients with disseminated histoplasmosis and is variably reversible with antifungal drug treatment.⁴⁴ Mucocutaneous involvement is uncommon in immunocompetent individuals, but may present as an ulcerated lesion, especially of the skin, oral mucosa, and/or gastrointestinal tract. Acute progressive disease is lethal without treatment.

Chronic Pulmonary Histoplasmosis

Chronic respiratory illness can develop in individuals with long-standing lung diseases, particularly emphysema or chronic obstructive lung disease, who acquire *H. capsulatum*. The disease can manifest after acute infection or due to reactivation of previously latent infection. Chronic histoplasmosis is characterized by indolent, progressive lung opacities, fibrosis, and cavitation⁴⁵ (Fig. 37-4). The majority of patients present with complaints of fever, weight loss, increasingly severe cough, and dyspnea, a presentation clinically and radiographically similar to that of cavitary tuberculosis.⁴⁶ Without therapy, the disease progresses in approximately 50% of affected individuals.⁴⁵

Transmissibility

In general, *H. capsulatum* is not contagious via the person-to-person route.⁴⁷ However, *H. capsulatum* has been transmitted to transplant recipients in the transplanted organ.⁴⁸ Reactivation disease can develop during immunosuppression in transplant recipients with latent infection with *H. capsulatum*. However, the risk for reactivation during immunosuppression is low ($<0.5\%$), even in high-risk groups such as renal or bone marrow transplant patients.⁴⁹ It is also worth noting that the mycelial growth of *H. capsulatum* is extremely hazardous to laboratory workers. The ability of the spores to disseminate widely and cause disease has recently been highlighted by a report of epidemic disease due to poor air filtration in buildings within a medical

Figure 37-4 Chronic histoplasmosis. Axial chest CT (A–D) shows upper lobe bronchovascular thickening with architectural distortion and areas of consolidation (arrowheads, B). Small nodules (single arrow, D) are also present. A cavity (double arrows, A) is present within the right upper lobe. The appearance closely resembles postprimary tuberculosis. (Courtesy Michael Gotway, MD.)

school in Texas.⁵⁰ Biosafety level 3 precautions are indicated when processing *H. capsulatum* mold cultures, soil, or other material potentially contaminated with conidia. In the diagnostic laboratory, biosafety 2 precautions are appropriate for the yeastlike form.

DIAGNOSIS

The “gold standard” for diagnosis is culture of *H. capsulatum*; however, this process takes a minimum of 1 week and growth may not be detected for approximately 1 month. Moreover, *H. capsulatum* is cultured from respiratory samples in fewer than 50% of patients with acute pulmonary histoplasmosis.⁵¹ In contrast, cultures are positive in 65% to 85% of patients with chronic pulmonary histoplasmosis. These data are complicated by the fact that studies have not critically examined the relative worth of different respiratory samples, although bronchoscopy with biopsy may provide the most effective testing mechanism because it can allow rapid visualization of the fungus in the tissue (see Fig. 37-2B). Direct observation of the fungus in respiratory secretions has high specificity but low sensitivity, and may be difficult because the fungus is located within macrophages. In disseminated disease, the fungus is usually detectable in bone marrow aspirates⁵² and can even be identified in peripheral blood, especially in buffy coats.⁵³

In the absence of positive cultures, serologic techniques such as immunodiffusion,⁵⁴ complement fixation,⁵⁵ enzyme immunoassay,⁵⁶ and radioimmunoassay⁵⁷ have been used to provide immunologic evidence of *H. capsulatum* infection. These serologic tests for the detection of either antibodies and/or antigen in clinical specimens (e.g., serum or urine) offer a rapid alternative method for the diagnosis of histoplasmosis (see Chapter 17). Although promising, polymerase chain reaction or mass spectroscopy methodologies

for detecting *H. capsulatum* are not yet developed for routine use. Skin testing with *H. capsulatum* antigens is not recommended for purposes other than epidemiologic studies.

In the United States, histoplasmosis is commonly diagnosed by antigen detection. *H. capsulatum* polysaccharide antigen can be detected by enzyme-linked immunosorbent assay (ELISA) in the urine of 92% of patients with disseminated histoplasmosis, 83% with acute disease, and 88% with chronic pulmonary histoplasmosis.⁵¹ Additionally, antigen can frequently be detected in the serum of patients with disseminated disease, suggesting that testing of both urine and blood will increase the sensitivity of testing. Testing of bronchoalveolar lavage fluid or cerebrospinal fluid can lead to the diagnosis of pulmonary or meningeal histoplasmosis, respectively. The assay is useful for following response to therapy and evaluating for disease relapse. The current *Infectious Diseases Society of America* (IDSA) guidelines recommend following antigen levels during and after treatment of histoplasmosis.⁵⁸ However, existing antigen assays may also detect related antigens from other endemic fungi, indicating that their interpretation must be undertaken in the context of other diagnostic information.⁵⁹

At present, the aforementioned tests are costly and impractical for use in less economically developed countries. A mainstay of diagnosis in many regions is an immunodiffusion test for detection of H and M precipitin bands utilizing *histoplasmin* (HMIN) as the antigen; HMIN is a well characterized antigen secreted by *H. capsulatum* mycelia and yeast.⁶⁰ The H antigen is a β -glucosidase⁶¹ and the M antigen is a catalase.⁶² Antibodies to these antigens can be detected by approximately 1 month after infection. The M band is detectable in approximately 75% of patients and can persist for years, whereas antibodies to the H antigen can be identified in less than 25% of patients and are undetectable after 6 months.⁶³ Complement fixation tests use

both HMIN and intact yeast cells, and this reaction becomes positive by approximately 3 weeks of disease and can persist for months to years.⁶⁴ A titer of 32 or greater is strongly suggestive of acute disease, although a titer of 8 in a patient with a high suspicion of histoplasmosis is consistent with disease. Titers are nondiagnostic in approximately 30% of patients with acute histoplasmosis and in 50% with disseminated disease. Most laboratories perform both the immunodiffusion and complement fixation tests concurrently to increase sensitivity. In immunocompromised patients with histoplasmosis, specific antibodies to the disease cannot be routinely detected, making these tests less sensitive in this population.⁶⁵

ELISA assays for the detection of antibodies in sera using HMIN have been established. ELISAs using HMIN compared to deglycosylated HMIN have sensitivities and specificities of 57% and 93% versus 92% and 96%, respectively.^{5,56} Treatment of purified HMIN with metaperiodate may further improve the utility of ELISA.⁶⁶

TREATMENT

Detailed information on antifungal drugs and their characteristics and uses is available in Chapter 38.

Comprehensive treatment recommendations for histoplasmosis have been made by the American Thoracic Society in 2011⁶⁷ and the IDSA in 2007.⁵⁸ The majority of individuals who acquire *H. capsulatum* are either asymptomatic or have a mild, self-limited flulike illness. Unless the patient is immunocompromised, there is no need for urgent administration of antimycotics under these circumstances.⁶⁸

Mild to Moderate Acute Pulmonary Histoplasmosis

If a patient has been symptomatic for more than 3 weeks or if a patient has moderate disease, itraconazole is appropriate. Itraconazole should be given as a loading dose of 200 mg thrice daily for 3 days followed by 200 mg twice daily for 6 to 12 weeks. Voriconazole and posaconazole can be considered for use in patients not responding to itraconazole.⁶⁹⁻⁷¹ Ketoconazole and fluconazole are less effective than itraconazole. Echinocandins should not be used to treat *H. capsulatum*.⁷²

Moderately Severe to Severe Acute Pulmonary Histoplasmosis

Compared to itraconazole, liposomal amphotericin is more effective in clearance of *H. capsulatum* in experimental histoplasmosis.⁷³ Liposomal amphotericin is favored over the conventional, deoxycholate formulations because the encapsulated liposomal amphotericin has less toxicity and a survival benefit has been shown with liposomal amphotericin compared to the conventional formulation in HIV/AIDS patients with histoplasmosis.⁷⁴ Liposomal amphotericin should be administered at 3 to 5 mg/kg daily for 1 to 2 weeks followed by itraconazole 200 mg thrice daily for 3 days and then 200 mg twice daily for 12 weeks. If liposomal amphotericin is not available, 0.7 to 1 mg/kg conventional amphotericin should be used. In patients with hypoxemia or significant respiratory distress, corticosteroids should be considered, particularly in HIV-infected individuals receiving antiretroviral therapy who are at risk for immune

reconstitution syndromes.⁷⁵ Methylprednisolone 0.5 to 1 mg/kg can be administered intravenously for the first 1 to 2 weeks together with antifungals. Alternatively, prednisone 40 to 60 mg/day can be given orally.

Chronic Cavitary Histoplasmosis

Itraconazole should be given as a loading dose of 200 mg thrice daily for 3 days followed by 200 mg twice daily for a minimum of 1 year. Extending treatment to 18 to 24 months may reduce the likelihood of disease recurrence due to relapse, which otherwise happens in approximately 15% of patients. Critically ill patients may benefit from initial treatment with amphotericin.⁷⁶

Disseminated Histoplasmosis

Treatment should be initiated with liposomal amphotericin, if available, for 1 to 2 weeks followed by itraconazole. Treatment should be continued for a minimum of 1 year. Occasionally, disseminated disease can be diagnosed in patients who have only mild to moderate symptoms. In immunocompetent individuals, itraconazole can be considered for initial therapy.

Immunocompromised Patients

Therapy with itraconazole 200 mg once or twice daily should be continued in immunocompromised patients whose immunosuppression cannot be reversed. In patients with HIV, therapy should be continued lifelong unless CD4 counts can be restored to levels greater than 200/ μ L.^{76a} Patients on maintenance itraconazole should have *Histoplasma* antigen testing performed periodically.

Drug Monitoring

Due to variable bioavailability, serum levels of itraconazole should be measured at 2 weeks of therapy and then every 3 to 6 months while on therapy.⁷⁷ Similarly, if voriconazole is being used as salvage, voriconazole levels should be monitored.⁷⁸

Management of Complications

Symptomatic pericarditis during acute histoplasmosis is generally managed with administration of nonsteroidal medications. Pericardiocentesis should be performed if hemodynamic compromise is present. In patients with hemodynamic compromise or persistent symptoms despite nonsteroidal therapy, prednisone should be administered and tapered over approximately 2 weeks. Patients treated with steroids should receive antifungal treatment, such as itraconazole for 6 to 12 weeks. Broncholithiasis (eFig. 37-4) is an uncommon condition in which a calcified lymph node erodes into the airway causing wheezing, dyspnea, or hemoptysis. If the patient fails to expectorate the broncholith, bronchoscopic removal may be required⁷⁹ and, rarely, if severe obstruction, fistulization, or massive hemoptysis develops, surgery is necessary.⁸⁰ No antifungal treatment should be administered for patients with broncholithiasis in the absence of other findings. Mediastinal lymphadenitis usually does not require treatment but, if there is severe disease with complications due to compression, patients should receive steroids and itraconazole. While there is no effective medical treatment for fibrosing mediastinitis, if it is unclear whether a patient has fibrosing mediastinitis or

mediastinal granulomatous disease due to *H. capsulatum*, then itraconazole should be administered at 200 mg orally once or twice a day for 12 weeks. Rheumatologic syndromes such as erythema nodosum are also generally managed with nonsteroidal therapy. However, if symptoms do not remit, prednisone and itraconazole should be given. No antimicrobial therapy is necessary when biopsy of a nodule incidentally shows *H. capsulatum* in an asymptomatic individual, especially when the fungus is not able to be cultured.

COCCIDIOIDOMYCOSIS

HISTORY AND EPIDEMIOLOGY

Coccidioidomycosis is a primary pulmonary infection caused by two species of *Coccidioides*, *C. posadasii* and *C. immitis*, which are endemic to the Central Valley of California, southwestern United States, and Central and South America where there are arid to semiarid life zones. The association of *Coccidioides* with human disease was first made by observing symptoms traditionally associated with “Valley fever” in a medical student exposed to a culture of the fungus in a laboratory. In the United States, it is estimated that approximately 150,000 persons are infected annually and that approximately 50,000 of these develop symptomatic disease.⁸¹ California and Arizona actively track cases of coccidioidomycosis and both states have reported significant increases in disease rates over the past decade,⁸¹ with Arizona having the most cases. In 2009, there were 10,233 laboratory-confirmed cases of coccidioidomycosis (155/100,000 population) reported in Arizona. Data from 2011 in California indicates that *Coccidioides* caused 5 hospitalizations/100,000 population.^{81a} It is also estimated that these fungi are responsible for approximately 2200 hospital admissions in the United States with an in-hospital mortality rate of 6% to 8%.⁶

Acquisition of the fungus is associated with disturbances of the soil. Purportedly, hyphae grow in moist soil and viable arthroconidia exist for protracted periods during dry periods. The fungus is thought to grow to a depth of approximately 8 inches. Arthroconidia are frequently aerosolized due to agriculture, excavation, or construction; individuals participating in these activities are at high risk for coccidioidomycosis in endemic regions. Additionally, soldiers marching behind tanks or other vehicles are at significant risk for inhalation of arthroconidia. Especially valuable insight into the epidemiology of coccidioidomycosis was obtained following an earthquake that caused landslides in a mountain range and dispersal of large dust clouds to a nearby community in Southern California in 1994.⁸² As an isolated exposure, limited in space and time, the transient dispersal of dust containing *Coccidioides* arthrospores revealed a clear dose dependence between exposure and disease rate (disease was highest in those closest to the source of dust clouds and that spent the longest time in dust clouds). In addition, when adjusted for exposure dose, symptomatic disease was more frequent in those older than 40 years of age. Individuals with advanced HIV infection or patients on corticosteroids or other immunosuppressants are at increased risk for severe disease. Disseminated disease

is also more likely in women in their third trimester of pregnancy and may be more likely in individuals of Filipino or African descent.⁸³

Disease is indistinguishable between the two species of *Coccidioides*. The two species were separated due to careful phylogenetic studies demonstrating divergence between the historically well described species *C. immitis* and the newer named species, *C. posadasii*.⁸⁴ There are certain phenotypic differences, such as differential growth rates under stress conditions, but they are morphologically indistinguishable and routine laboratory testing does not separate the species. Initially, *C. immitis* was defined as limited to the San Joaquin Valley in California whereas *C. posadasii* was present diffusely throughout the endemic regions detailed for the fungus; more recent data suggest that there is significant overlap in the distribution of the two species.

Coccidioidomycosis was first described in 1892 by Alejandro Posadas in an Argentinian soldier.⁸⁵ The organism was initially thought to be a protozoan of the order Coccidia, leading to its name. *Coccidioides* was not confirmed as a fungus until 1900.⁸⁶

PATHOGENESIS

The specialized spores, arthroconidia, arise from hypha and form chains of cells. The arthroconidia are 2 to 4 $\mu\text{m} \times 5$ to 6 μm ovoid cells, and the chain usually consists of an intact multinucleate arthroconidia alternating with a degenerated cell. The thinner wall of the degenerated cell is readily disrupted when the chain is disturbed, such as during a wind storm, landslide, or construction, and individual or small collections of arthroconidia can then be aerosolized and subsequently inhaled.⁸⁷ The arthroconidia undergo morphogenesis in humans or under specialized laboratory conditions at 37°C into a unique structure, a spherule. An arthroconidia converts to a spherule over approximately 2 to 4 days with the arthroconidia first developing into a round cell. Then, the spherule forms by successive growth and segmentation into an oval structure of 20 to 150 μm in diameter that contains dozens to hundreds of 2- to 4- μm endospores (Fig. 37-5F). Rupture of mature spherules leads to the release of endospores that, in the absence of effective host immunity, can develop locally into spherules or disseminate through hematogenous or lymphatic routes to cause disease in other tissues. Notably, arthroconidia and septate hyphae can be identified in some patients with chronic disease, especially those with diabetes, in whom there is low oxygen tension and tissue necrosis.

Coccidioides cause disease in immunocompetent or immunocompromised individuals, with disease severity typically being worse in immunodeficient patients.⁸⁸ Initial host responses to arthroconidia include influxes of both macrophages and neutrophils. Neutrophils may stimulate arthroconidia to convert into spherules,⁸⁹ yet they can impede morphogenesis after the development of antibody responses.⁹⁰ The oxidative burst is effective against arthroconidia and immature, but not mature, spherules. Additionally, after conversion to a spherule, the sheer size of this form precludes its phagocytosis by neutrophils or macrophages. In tissues, organized necrotizing granulomatous inflammation predominates, with T and B lymphocytes present at the margins of the lesions.

Figure 37-5 Disseminated coccidioidomycosis in an immunosuppressed patient. **A**, Frontal chest radiograph shows numerous, randomly disseminated nodules bilaterally consistent with a miliary pattern. **B**, Chest CT shown in lung windows confirms the miliary pattern. Axial chest CT shown in soft tissue (**C**) and bone (**D**) windows demonstrates bilateral paraspinal masses (arrows) associated with vertebral body destruction. The CT image shown in bone windows (**D**) reveals the vertebral body destruction (arrow) to advantage. **E**, Photomicrograph shows characteristic giant spherule of coccidioidomycosis in a lung biopsy. (Hematoxylin and eosin stain; original magnification $\times 450$.) (Courtesy Michael Gotway, MD.)

T lymphocyte responses are critical for protection against *Coccidioides*: Th1 responses are protective, whereas Th2 responses are less effective and may drive adverse outcomes. Consistent with this, lymphocyte secretion of interferon- γ is associated with resistance, whereas interleukin-4 is associated with susceptibility.⁹¹ The roles of other T-helper lymphocyte subsets in human immunity to *Coccidioides* is not yet known. Consistent with the importance of CD4⁺ T lymphocytes, severe disease is more common in patients with advanced HIV infection.

Individuals with prior symptomatic infection are generally protected against reinfection with either species of *Coccidioides*. However, waning immunity, such as in advanced HIV infection, or treatment with immunosuppressants can lead to reactivation of latent lesions or abolish protection against reinfection.

CLINICAL MANIFESTATIONS

Disease manifestations can range from asymptomatic acquisition to pneumonia, cavitary pulmonary disease, or disseminated infection that can involve skin, bone, central nervous system, and visceral organs.⁹² Of individuals infected with *Coccidioides*, 60% to 80% are either asymptomatic or have mild respiratory symptoms.⁹³ However, 15% to 35% of individuals develop respiratory symptoms,

1 to 4 weeks after inhalation of the arthroconidia. Although the majority of these cases resolve without sequelae, approximately 5% develop persistent or progressive pulmonary disease (eFig. 37-5). Furthermore, approximately 1% to 5% will have disseminated disease, which is more common in pregnant women, people of African descent, and immunocompromised individuals⁸⁸ (see Fig. 37-5).

Pulmonary Coccidioidomycosis (Valley Fever or Primary Coccidioidal Infection)

Primary symptomatic infection is typically a subacute pulmonary disease. The initial symptoms resemble influenza, with fever, cough, dyspnea, fatigue, headaches, myalgias, and arthralgias. Patients whose disease progresses to pneumonia typically have segmental or lobar disease, and mediastinal and/or hilar lymphadenopathy is characteristic (eFig. 37-6). In areas with high endemicity, approximately 15% to 30% of cases of community-acquired pneumonia may be due to *Coccidioides*.⁹⁴ Dermatologic immunologic manifestations such as erythema nodosum or erythema multiforme are associated with a favorable host response to the fungus. Pleural effusions complicate approximately 5% to 15% of cases, although the presence of an effusion does not correspond to increased severity of disease. The pleural fluid can be either transudative or exudative, and lymphocytes and eosinophils predominate. Coccidioidal

Figure 37-6 Coccidioidomycosis peripheral cavity with rupture into pleural space and empyema and bronchopleural fistula. **A**, Frontal chest radiograph shows a large left hydropneumothorax; note air-fluid level. The patient was treated with extended tube thoracostomy, antifungal therapy, and eventually video-assisted thoracoscopic pleural space débridement. *Coccidioides* spherules were recovered from the left pleural space. **B**, One year later, the chest CT shows a uniformly thin-walled, peripheral cavity (arrow) characteristic of *Coccidioides immitis* pulmonary infection. (Courtesy Michael Gotway, MD.)

empyema may develop, requiring aggressive interventions (Fig. 37-6A).

Acute Respiratory Failure and Acute Respiratory Distress Syndrome

Acute respiratory failure or *acute respiratory distress syndrome* (ARDS) due to coccidioidomycosis is atypical and is generally seen in the setting of advanced immunodeficiency. However, massive exposures to arthroconidia during construction or archeological excavation can lead to rapidly progressive respiratory failure. ARDS is even more uncommon (eFig. 37-7), but mortality rates for this form approach 100%.

Disseminated Coccidioidomycosis

Disseminated disease may be acute or chronic. Disease may be multifocal or restricted to a single extrapulmonary site. Prognosis of infection at a single extrapulmonary site is typically better than for multifocal disease, except in the case of meningitis (eFig. 37-8). Multifocal disease has a mortality rate of up to 50%. Meningitis is frequently progressive and shunts are often required to manage increased intracranial pressures.

An unusual presentation is miliary coccidioidomycosis in which numerous small granulomas develop throughout the lungs and other organs. Radiographs depict 3- to 4-mm nodules (eFig. 37-9) throughout the lung fields, indistinguishable in appearance from miliary tuberculosis. This presentation is a risk factor for the development of ARDS.

Pulmonary Nodule (Coccidioidoma)

A coccidioidoma is usually found as a single nodule (eFig. 37-10) in the peripheral lung tissue, and can be difficult to distinguish from a malignant lesion. To minimize unnecessary invasive procedures, physicians should consider the diagnosis of coccidioidomycosis in patients with a history of residence in an endemic area. In this setting, review of prior chest radiographs can be especially worthwhile in determining the likelihood of malignancy or healed fungal infection.

Cavitary Coccidioidomycosis

Although uncommon, thick or thin-walled (see Fig. 37-6B, eFig. 37-11B-D) cavities may develop during resolution of coccidioidomycosis. Cavities likely form because of infarction or liquefactive necrosis. If the cavities are peripheral, there are risks for fistula formation and/or pneumothorax (see Fig. 37-6). Larger cavities may be resected to prevent cavity rupture. Smaller cavities can be monitored radiographically (see eFig. 37-11B-D). A second cavitary disease process seen with coccidioidomycosis is a chronic fibrocavitary pneumonia (eFig. 37-12) characterized by multilobar opacities and cavities. This form is more common in patients with diabetes, and fever, chills, night sweats, and weight loss are typical.

Transmissibility

Person-to-person transmission is rare and restricted to a few instances of accidental exposure to arthroconidia from a patient with coccidioidal osteomyelitis, or organ transplantation from an infected donor.^{95,96} The infectivity of *Coccidioides* is noteworthy, and occupational infection is a risk to laboratory workers.⁹⁷ The association of Valley fever with *Coccidioides* was made in 1929 when a medical student opened a petri dish with mycelial *Coccidioides* and subsequently developed coccidioidomycosis. Thus, cultures of *Coccidioides* should only be handled under BSL3 conditions.

DIAGNOSIS

The gold standard for diagnosis remains isolation of *Coccidioides* from infected tissues; however, patients frequently do not produce sputum and the cultures take a minimum of a week to detect growth and more frequently take several

weeks. Direct examination of sputum is not sensitive. Cultures are most often used in hospitalized patients.

The most commonly used diagnostic tests depend on serologic assays for the presence of antibodies to *Coccidioides* antigens. However, antibody responses may lag behind clinical symptoms, especially in immunocompromised individuals. Hence, negative antibody testing in such patients does not exclude infection with *Coccidioides*. The immunodiffusion assays for IgM and IgG antibodies are commonly used, because they provide the greatest specificity. A commercial enzyme-linked immunoassay can detect IgM and IgG antibodies to *Coccidioides* and is more sensitive but less specific than the immunodiffusion assay. A complement fixation method that detects IgG antibodies to *Coccidioides* chitinase is also used in many laboratories. Either immunodiffusion or complement fixation assays can be used to monitor responses to treatment. Molecular methodologies have not yet been validated for *Coccidioides*. Additional information on serologic and other diagnostic testing for coccidioidomycosis is available in Chapter 17.

TREATMENT

Comprehensive treatment recommendations for coccidioidomycosis have been made by the American Thoracic Society in 2011⁶⁷ and the IDSA in 2005.⁸¹ An update in recommendations is currently in progress by the IDSA and is projected to be available by Spring 2015.

Uncomplicated Acute Pneumonia

Mild to moderate pulmonary disease in an individual with a normal immune system is not an indication for treatment, because there is no evidence that antifungal treatment hastens resolution of symptoms.⁹⁸ However, patients with HIV, pregnant women, or patients who are otherwise immunosuppressed should be treated. In immunocompetent individuals, treatment is recommended if symptoms persist for more than 8 weeks or if the patient has lost more than 10% total body weight, has night sweats for more than 3 weeks, or if disease is present in more than half of a single lung, is multilobar, or if hilar lymphadenopathy persists. Additionally, complement fixation titers greater than 16 often prompt treatment. If antifungal therapy is initiated for mild to moderate disease, it is generally administered for 3 to 6 months. If untreated disease progresses to chronic fibrocavitary pneumonia, a minimum of 1 year of antifungal therapy is recommended. Long-term azole therapy should be considered for immunocompromised individuals.

Treatment is usually with either oral fluconazole (400 to 800 mg/day) or itraconazole (200 mg two or three times daily); the higher doses are usually reserved for more complicated cases. Drug levels for itraconazole should be obtained after 2 weeks of therapy, due to its variable bioavailability.⁷⁷ In more severe disease, lipid formulations of amphotericin B (2 to 5 mg/kg daily) or conventional amphotericin B (0.5 to 1.5 mg/kg daily) may be preferred, but data from randomized comparative trials are lacking. There are insufficient data to evaluate the efficacy of voriconazole and posaconazole for coccidioidomycosis, although there are reports of responses in otherwise refractory cases. Echinocandins are not recommended, due to intrinsic resistance of *Coccidioides* to this class of drugs. Even in the

absence of treatment, patients should be monitored every 3 to 6 months for 2 years to document resolution of radiologic evidence of disease and confirm the absence of pulmonary or other complications.

Complicated Pneumonia with or Without Dissemination

Diffuse disease, particularly reticulonodular pneumonia or miliary opacities, is treated initially with an amphotericin formulation or high-dose fluconazole; the latter is also used after an initial response is achieved in patients initiated on amphotericin. If dissemination is present, especially if the patient has meningitis, treatment with fluconazole is the preferred approach. Corticosteroid therapy may be useful in patients with severe pulmonary coccidioides with ARDS using approaches validated for *Pneumocystis jirovecii*: prednisone 40 mg two times daily for 5 days, then 40 mg daily, and then 20 mg a day for 11 days. For complicated pneumonia, recovery is frequently slow, with symptoms resolving over weeks. Treatment is for a minimum of 1 year.

Pulmonary Nodule

If a solitary nodule is identified as due to *Coccidioides* after a biopsy, there is no need to administer antifungal therapy or resect the lesion. If the nodule was excised, no additional treatment is necessary. Treatment with an azole should be considered in a patient with a nodule if the patient subsequently becomes immunocompromised.

Pulmonary Cavity

Asymptomatic cavitary lesions should be followed clinically and radiographically (see eFig. 37-11). If a patient is symptomatic or has an elevated antibody titer, treatment with an azole for 3 to 6 months should be considered although 12 to 18 months may be necessary for immunocompromised individuals. Larger cavities are often resected after 2 or more years if they have not resolved. Bacterial superinfection is a complication that requires aggressive antimicrobial treatment, and subsequent resection of the cavity is prudent. Cavity rupture is rare, but can lead to pyopneumothorax (see Fig. 37-6A and B) requiring antifungal therapy and decortication.

BLASTOMYCOSIS

HISTORY AND EPIDEMIOLOGY

Blastomyces dermatitidis, the causative agent of blastomycosis, is a dimorphic fungus endemic to North America along the Mississippi, Ohio, and St. Lawrence rivers as well as in regions adjacent to the Great Lakes. The fungus also rarely causes sporadic disease in parts of Africa, although the African isolates studied vary in antigen expression relative to North American isolates.⁹⁹ *B. dermatitidis* is a soil-based fungus associated with riverbanks.¹⁰⁰ Hence, risk factors for acquisition of the fungus include exposures to waterways, soils, or woods: approximately 30% of forestry workers in endemic areas of Minnesota and Wisconsin have serologic evidence of prior infection. Infection with *B. dermatitidis* is thought to follow inhalation of aerosolized conidia, and the common clinical manifestations include pneumonia, skin

and bone lesions, and involvement of the genitourinary tract.

The rates of disease vary significantly with regions, even within the same state. For example, a 1992 study of 11 years of laboratory-confirmed blastomycosis showed that the rate of disease in Wisconsin is approximately 1.4 cases per 100,000, but there are regions where there are approximately 40 cases per 100,000.¹⁰¹ Most cases are sporadic, but outbreaks have been reported. In 2003, there were 771 patients hospitalized with a diagnosis of blastomycosis, with a 6% mortality rate in hospitalized adults.⁶

Thomas Gilchrist described blastomycosis in 1894,¹⁰² and blastomycosis is also referred to as Gilchrist disease. Interestingly, Gilchrist misidentified the fungus as a protozoan, but later corrected this error. Early descriptions emphasized the cutaneous manifestations, so blastomycosis was initially considered primarily a localized dermatologic condition rather than a systemic infection.

PATHOGENESIS

B. dermatitidis exists in a mold form in the environment or under laboratory conditions at approximately 25°C. Inhalation of conidia or cultivation at 37°C results in transformation into yeast cells (8 to 12 µm in diameter), which bud with a broad-based connection between the mother and daughter cells (see Figs. 37-7B and 17-6). In tissue, yeast forms that are 25 to 40 µm in diameter can also be seen. After inhalation, conidia are engaged by neutrophils and macrophages, which can kill the cells and/or inhibit conidial morphogenesis.¹⁰³ The yeast form is more resistant to killing, especially by neutrophils¹⁰⁴ and the yeast directly inhibit the enzymatic activity of macrophage inducible nitric oxide synthase.¹⁰⁵ The yeast cells can disseminate from the lungs via the bloodstream or lymphatics to any tissue. In tissues, neutrophilic infiltrates are seen early in disease followed by a granulomatous response characterized by multinucleated giant cells and noncaseating granulomas. Activation of effective T-cell-mediated responses is required to halt disease.¹⁰⁶ BAD-1, an essential virulence factor and adhesin of *B. dermatitidis*, promotes disease by suppressing the host inflammatory response through inhibition of TNF-α.¹⁰⁷ Hence, the outcome of this dynamic between host and pathogen responses dictates disease manifestations. There are two distinct genetic groups of *B. dermatitidis*; Group 1 isolates usually cause disease restricted to the lungs whereas Group 2 isolates have an increased propensity to cause disseminated disease.¹⁰⁸

CLINICAL MANIFESTATIONS

Pulmonary infection with *B. dermatitidis* leads to asymptomatic infection, acute or chronic pneumonia, or disseminated disease. Infection is asymptomatic in approximately 50% of individuals^{109,110}; symptomatic disease generally develops after an incubation period of 4 to 8 weeks or more. Some studies suggest a seasonality to blastomycosis, which corresponds to outdoor activities in the endemic regions, resulting in infections at the end of summer into early fall, with these individuals subsequently presenting with extrapulmonary disease in the next year.¹¹¹ The initial mild presentations manifest with influenza-

like symptoms, including fever, cough, myalgias, and arthralgias.¹¹²

Acute Pulmonary Blastomycosis

The diagnosis of pulmonary blastomycosis is often delayed because the manifestations are not sufficiently different from those of community-acquired bacterial pneumonia to raise suspicion of the diagnosis. In addition to fever and cough, mild hemoptysis may be present.¹¹³ The disease can resolve, but the incidence of resolution without subsequent dissemination is unknown. Radiologic findings can vary greatly in acute disease and these manifestations can also be present in chronic disease. The most common presentation is focal (Fig. 37-7A) or diffuse airspace consolidation.^{42,114} However, even asymptomatic patients can have mass lesions, cavities (eFig. 37-13), or single or multiple (eFig. 37-14) nodules. Acute progressive blastomycosis is infrequent, but pulmonary disease can progress to ARDS, which is associated with mortality rates of approximately 78%,¹¹⁵ and with mortality typically seen within 1 week of presentation to medical attention. Progressive disease can manifest as diffuse multilobar opacities, endobronchial

Figure 37-7 Focal pulmonary blastomycosis. **A**, Axial chest CT shows a lobar left upper lobe consolidation pattern. **B**, Micrograph shows *Blastomyces dermatitidis* in fresh sputum after 10% potassium hydroxide digestion. Note the broad neck of attachment, the double refractile cell wall, and the multiple nuclei. (Original magnification ×1000.) (A, Courtesy Jeff Kanne, MD, Associate Professor, Thoracic Imaging, Department of Radiology University of Wisconsin School of Medicine and Public Health.)

infection, or miliary blastomycosis. Approximately half of the patients with severe disease are immunosuppressed,¹¹⁶ including cancer patients, transplant recipients (eFig. 37-15), patients on TNF antagonists, or individuals with advanced HIV infection.

Chronic Pulmonary Blastomycosis

Similar to histoplasmosis and coccidioidomycosis, blastomycosis can present as a chronic pneumonia that is indistinguishable from tuberculosis or from pulmonary malignancies. Patients with chronic blastomycosis frequently report being ill for more than 2 months with fever, weight loss, night sweats, cough and chest pains.^{110,117} The most frequent radiographic findings include consolidations, mass lesions and interstitial fibronodular opacities.¹¹⁴ Cavitation is uncommon, although small pleural effusions may be present.

Extrapulmonary Disease

The reported incidence of extrapulmonary disease has been between approximately 20% and 75% of cases, with the upper range in patients with chronic untreated blastomycosis.^{101,110} Due to more rapid diagnosis, overall rates of disseminated disease are presently closer to 20% to 25%. The most frequent site of dissemination is the skin, seen in 40% to 80% of cases of extrapulmonary disease. The typical presentation is a crusting verrucous lesion with a central draining microabscess (Fig. 37-8); there may also be nodular, pustular, or ulcerative lesions.¹¹⁸ Multiple lesions are typically present and mucous membranes can also be involved. Cutaneous lesions can overlie bone lesions that produce sinus tracts to skin. *B. dermatitidis* infects bone in approximately 5% to 50% of patients with extrapulmonary disease; approximately 75% of patients with osseous disease have concomitant active pulmonary involvement.¹¹⁹ Bone radiographs typically reveal focal osteolytic lesions without periosteal reactivity, but some lesions can be highly destructive. The third most frequent site of extrapulmonary disease is the genitourinary tract, seen in 10% to 30% of cases. The incidence is higher in males where disease frequently mani-

festes as blastomycosis of the prostate, testicle, or epididymis. *B. dermatitidis* can affect any tissue, but the most formidable disease is that of the central nervous system, seen in up to 10% of extrapulmonary blastomycosis and generally in immunosuppressed patients. Before the availability of combination antiretroviral therapy, 40% of individuals with AIDS and blastomycosis developed central nervous system disease with approximately 40% mortality.¹²⁰ Frequency of severe or pulmonary disease is greater and mortality is increased in Aboriginal Canadians and in those with cellular immunodeficiencies and/or advanced age.¹¹⁷

Transmissibility

B. dermatitidis is generally not transmissible person-to-person. However, there have been rare cases of presumed conjugal transmission as well as acquisition in utero. Dogs are at high risk for blastomycosis in endemic areas; a vaccine utilizing the BAD-1 protein has been shown to be protective in dogs¹²¹; this is a candidate platform for a human vaccine. Bites from infected dogs have led to cutaneous blastomycosis in humans.

DIAGNOSIS

The gold standard for diagnosing blastomycosis is culture.¹¹⁹ Growth can be detected after several days to weeks on mycologic medium. However, cultures are problematic because, even with specimens obtained by bronchoscopy, the rate of positive culture is no higher than 67%. Direct observation is the most rapid method for diagnosis. Microscopic examination of *potassium hydroxide* (KOH)-treated respiratory specimens can reveal *B. dermatitidis* yeast forms (see Figs. 37-7B and 17-6) in up to 46% of patients. Cytologic evaluation with Papanicolaou or other stains can detect *B. dermatitidis* in up to 71% of patients with pulmonary disease. Histologic examination can also be helpful.

A commercial ELISA to detect *Blastomyces* antigen, similar to the *Histoplasma* urinary assay, has recently been developed that has a reported sensitivity of approximately 93%, although clinical information on the subjects was not provided.¹²² Antigenuria can be detected in patients with pulmonary or extrapulmonary disease, and testing can also be performed on serum, plasma, cerebrospinal fluid, bronchoalveolar lavage fluid, or other sterile fluids. The test is also reportedly useful to follow response to treatment or assess for relapse. However, there is significant cross-reactivity with *H. capsulatum* and other dimorphic fungi. A new promising ELISA based on the immunodominant BAD-1 protein specific for this fungus has recently been reported.^{122a} Although commercial antibody tests are available, they lack clinical utility.

TREATMENT

Comprehensive treatment recommendations for blastomycosis have been made by the American Thoracic Society in 2011⁶⁷ and the IDSA in 2008.¹²³ In an immunologically normal individual, acute disease is often mild and resolves without antifungal therapy. Nevertheless, clinical guidelines suggest that treatment should be considered for any patient, because it is not currently possible to determine the likelihood of extrapulmonary dissemination.

Figure 37-8 Cutaneous lesion of blastomycosis. (Photo courtesy Bruce Klein, MD, University of Wisconsin Departments of Pediatrics and Medical Microbiology and Immunology.)

Mild to Moderate Blastomycosis

Current consensus is that mild to moderately ill patients with pulmonary blastomycosis should receive itraconazole (200 mg twice daily) for 6 months. Levels of itraconazole should be verified after 2 weeks of administration and periodically during treatment, due to variations in blood levels achieved.⁷⁷ Therapy for mild to moderate pulmonary blastomycosis is not altered if there is nonmeningeal dissemination, except in the setting of bone disease, when therapy is extended to 1 year.

Moderately Severe to Severe Blastomycosis

Patients with moderately severe to life-threatening pulmonary blastomycosis, including ARDS, should initially be treated with liposomal amphotericin B (5 mg/kg/day) or conventional amphotericin (0.7 to 1 mg/kg/day) until clinical improvement is evident (usually 1 to 2 weeks) and then switched to itraconazole (200 mg twice daily for 6 to 12 months). Liposomal formulations are generally preferred. Although there are limited data to support the use of corticosteroids, administration of steroids in the setting of extensive disease with hypoxemia may be beneficial. If patients have meningitis, amphotericin with or without fluconazole (800 mg daily) or itraconazole (200 mg twice daily) is used initially (typically for 4 to 6 weeks) followed by 6 to 12 months of treatment with an azole, with many experts favoring a minimum of 12 months. Voriconazole may be considered for use in refractory disease. Echinocandins should not be used, due to intrinsic resistance of *Blastomyces* to this class of drugs. Immunocompromised patients should be treated for a minimum of 12 months or continued indefinitely if the immunodeficiency is irreversible.

PARACOCOCCIDIOIDOMYCOSIS

EPIDEMIOLOGY

Paracoccidioides brasiliensis, the causative agent of paracoccidioidomycosis, is a dimorphic fungus that is endemic in

southern Mexico, Central America, and South America. *P. brasiliensis* is the major causative agent of systemic mycosis in Latin America,¹²⁴ and it is a leading cause of disability and death among young adult rural workers.¹²⁵ A 2001 analysis estimated that approximately 10 million people were infected with *Paracoccidioides* spp.¹²⁶ However, symptomatic disease would be expected to develop in only approximately 1% to 2%, with pulmonary disease as the most common form. Nine-banded armadillos that burrow in the soil of endemic regions are also infected with high frequency, which provides evidence for a soil reservoir of the fungus.

Phylogenetic analyses have recently led to the separation of *Paracoccidioides brasiliensis* and *Paracoccidioides lutzii* (formerly *P. brasiliensis* isolate 01).¹²⁷ The manifestations of infection by these two species are indistinguishable.

PATHOGENESIS

In the environment or under laboratory conditions at less than 28°C, *P. brasiliensis* grows as a mycelium that produces chlamydoconidium, terminal conidia, and arthroconidia, with arthroconidia believed to be the infectious agent. In tissues or at greater than 37°C, yeast forms predominate, which typically are a 5- to 30-μm diameter ovoid mother cell displaying several blastoconidia (forming a “pilot’s wheel”) (Fig. 37-9).

Interestingly, the ratios of clinical disease in males to females average approximately 13:1, but can be as high as 150:1. *P. brasiliensis* expresses β-estradiol receptors on the conidial cell membrane; binding to these receptors inhibits morphogenesis to the yeast form, blocking disease progression.¹²⁸ Women are not protected against infection, but clinical disease is less likely. Smoking may also exacerbate disease, although the mechanism is not clear.

The initial host response to *P. brasiliensis* consists predominantly of neutrophils followed by recruitment of macrophages and granuloma formation. This process is highly regulated by cellular responses; Th1-based responses are protective whereas Th2 type responses are common in patients unable to control their disease. The impact of cellular immunity is further underscored by the increased

Figure 37-9 Pulmonary paracoccidioidomycosis infection. **A**, Frontal chest radiograph shows bilateral poorly defined masses. **B** and **C**, Axial chest CT images confirm the presence of bilateral nodules, masses, and masslike areas of consolidation. Percutaneous transthoracic needle biopsy subsequently proved paracoccidioidomycosis infection. **D**, *Paracoccidioides brasiliensis* yeast forms. Several large mother cells with associated blastoconidia (forming a “pilot’s wheel”) are present. (Gomori methenamine silver stain.) (**A–C**, Courtesy Michael Gotway, MD; **D**, photomicrograph courtesy Dr. Carlos Taborda, PhD, University of São Paulo, Brazil.)

incidence of disseminated disease in patients with AIDS. A review of deaths in 3583 AIDS patients due to systemic mycoses in Brazil from 1996 to 2006 revealed that paracoccidioidomycosis was responsible for approximately 50% of deaths.¹²⁹ Individuals on steroids, patients receiving chemotherapy, or patients who have received organ transplants are also at increased risk for severe disease.

CLINICAL MANIFESTATIONS

As noted, the vast majority of infections are asymptomatic, and the initial acquisition is largely believed to happen in childhood. There are two patterns of disease manifestation: the acute or subacute form (also called juvenile type) and the chronic form (or adult type). The juvenile type is seen in less than 10% of cases and most frequently develops in the age range from prepubescent teenagers to adults younger than 30 years old. Patients are acutely ill, often presenting with fever, weight loss, and lymphadenopathy. Additionally, patients can have hepatosplenomegaly, intestinal lesions, and bone disease with or without bone marrow dysfunction. In contrast, the chronic form involves the lungs in approximately 90% of patients, likely due to reactivation of latent disease. However, new acquisition of the fungus is possible. Disease is confined to the lung in approximately 25% of patients, with the remainder presenting with multifocal disease, including dissemination to mucous membranes, lymph nodes, skin, adrenals, and other organs. Disease manifestations can mimic tuberculosis, which can also coinfect approximately 10% of these patients.¹³⁰

Radiologic findings are nonspecific and range from diffuse opacities to masses (see Fig. 37-9) and cavities (eFig. 37-16). Lymphadenopathy is often a prominent feature. Long-term complications develop in more than 50% of patients with significant chronic pulmonary disease, most often owing to impaired respiratory function due to fibrosis or cavities (eFig. 37-17); cor pulmonale is common in these patients. Additionally, compression of structures, such as the trachea, can develop. Single residual nodules without calcification are common.

DIAGNOSIS

The diagnosis can be confirmed through detection of antibodies. The major diagnostic antigen is a 43-kD glycoprotein of *P. brasiliensis* (gp43, a laminin-binding protein); antibodies can be identified in serum of approximately 90% of patients.^{131,132} However, culture and microscopy are generally used for diagnosis in endemic areas. As noted, the yeast form has distinct shapes that can be identified in up to 90% of sputum, exudate, or pus samples from patients with chronic paracoccidioidomycosis (see Fig. 37-9D). Culture remains a problem because the fungus routinely takes 20 to 30 days to grow on mycologic agar; culture is thus less useful in making clinical decisions.

TREATMENT

Optimal treatment regimens for *P. brasiliensis* have not been formally validated.^{67,130} However, in seriously ill patients with dissemination, amphotericin therapy is used as initial

therapy. Amphotericin is either continued until a total dose of 2 g is achieved or until the patient improves and can be switched to an oral drug. Treatment with amphotericin B alone, even when a cumulative dose of 2 g is achieved, is associated with relapse in 25% to 30% of cases of paracoccidioidomycosis. Ketoconazole (200 to 400 mg daily) or itraconazole (200 to 400 mg daily) are the most commonly used azoles for paracoccidioidomycosis. Itraconazole is currently preferred, because its use is associated with lower relapse rates than is ketoconazole (3% to 5% vs. 10%) and is better tolerated by most patients. Voriconazole and posaconazole may also have utility, although in one published study, voriconazole was neither better tolerated nor more efficacious than itraconazole.¹³³ Azole regimens range from 6 months to 18 to 24 months, depending on the rate of clinical response and evidence of fungal clearance as reflected by serologic testing. *P. brasiliensis* is also susceptible to sulfonamides, although use of these drugs for treatment requires very prolonged courses (3 to 5 years) and is associated with relapse rates of 20% to 25%.

SPOROTRICHOSIS

Sporotrichosis is principally due to the dimorphic fungus *Sporothrix schenckii*, which is globally ubiquitous and grows in decaying vegetation, sphagnum moss, soil, and other environmental niches. The vast majority of infections arise after cutaneous inoculation of the fungus. There are several additional species of *Sporothrix* associated with human disease, particularly *S. brasiliensis*, *S. globosa*, and *S. mexicana*.¹³⁴ *S. brasiliensis* is responsible for infections associated with cat scratches in the state of Rio de Janeiro, Brazil. Pulmonary disease is rare, but can develop after inhalation of conidia. Such cases of pulmonary disease primarily present in middle aged men; risk factors include chronic obstructive lung disease and alcoholism. Radiographically, pulmonary sporotrichosis appears as cavitory and fibronodular disease.¹³⁵ Disseminated disease is rare and is primarily seen in severely immunocompromised individuals, especially in individuals with advanced HIV infection.

The standard for diagnosis of invasive sporotrichosis is culture, although *Sporothrix* typically requires 1 to 4 weeks for detectable growth from a clinical sample. Microscopic examination of biopsy material often fails to reveal the organism, likely due to the small number of organisms that are needed to cause disease. The ovoid yeast cells are 3 to 5 µm in diameter, and eosinophilic projections from the yeast may be present, resulting in a characteristic “asteroid body.” Severe to life-threatening pulmonary sporotrichosis should be initially treated with amphotericin B (3 to 5 mg/kg/day of lipid amphotericin or 0.7 to 1 mg/kg of conventional amphotericin).¹³⁶ Once the patient's condition has stabilized, typically within 2 weeks, itraconazole (200 mg twice daily) can be administered for at least 1 year of total antifungal therapy. Adjunctive surgery may be useful in the management of severe focal disease. If the disease is less severe, itraconazole can be used as initial therapy.¹³⁵ Serum levels of itraconazole should be verified after 2 weeks of administration and periodically thereafter. Treatment is generally from 3 to 6 months. Antifungals used for other manifestations of sporotrichosis, such as terbinafine,

saturated solution of potassium iodide, or fluconazole, are not effective for pulmonary disease.

PENICILLIOSIS

Penicillium marneffei, is a dimorphic fungus responsible for a systemic mycosis geographically restricted to southeast Asia, India and southern China, especially in individuals with HIV¹³⁷ (Chapter 90). In the environment, *P. marneffei* exists as a mold, whereas in tissues it is in a yeastlike form (arthroconidium), which is notable for replicating by fission. Penicilliosis is the third most common opportunistic infection in individuals with HIV in parts of tropical Asia, after tuberculosis and cryptococcosis. Although the majority of cases are seen in the setting of advanced HIV infection, disease also develops in patients with immunosuppression due to malignancy or medical therapies as well as in patients with underlying lung disease. Patients typically present with disseminated disease characterized by fever, weight loss, generalized lymphadenopathy, skin lesions (frequently papules with central necrosis), and hepatomegaly. The pathobiology of *P. marneffei* is comparable to that of histoplasmosis, in that *P. marneffei* survives within macrophages and manifests a similar spectrum of disease. Diagnosis is typically achieved by culture and microscopy. The simplest diagnostic approach is via biopsy of skin lesions or lymph nodes and histologic assessment for fission arthroconidium. *P. marneffei* can also be visualized in peripheral blood smears in patients with fulminant disease. Initial therapy is with amphotericin B followed by itraconazole.¹³⁸

Key Points

- Pulmonary infections due to endemic dimorphic fungi are more common than are typically considered in routine differential diagnoses.
- Any time that *Mycobacterium tuberculosis* is in a differential diagnosis, endemic dimorphic fungi should also be considered; indeed, dimorphic fungi cause similar numbers of deaths in the United States annually as tuberculosis.
- The common endemic dimorphic fungi in North America are *Histoplasma*, *Coccidioides*, and *Blastomyces*; in South America, the common endemic dimorphic fungus is *Paracoccidioides*.
- Disease may develop acutely after acquisition of the dimorphic fungi or remain latent for protracted periods with subsequent activation in the setting of immunologic suppression.

- Disease manifestations of dimorphic fungi range from mild, flulike illnesses to life-threatening systemic processes. The endemic fungi can cause disease in any tissue, although histoplasmosis frequently involves the reticuloendothelial system; coccidioides involves skin, bone, and central nervous system; and blastomycosis involves skin and bones.
- Disease severity is highly associated with the size of the inoculum as well as host immunity. Patients with defects in cellular immunity, especially of CD4⁺ T cells (i.e., advanced HIV infection), or with tumor necrosis factor alpha blockade, are at risk for more severe disease.
- Diagnosis may be challenging, because direct identification has a poor sensitivity and cultures may require up to 4 weeks before growth is detected. Diagnosis frequently utilizes serologic testing to detect antigen or antibody. Identification based on fungal morphology in tissue samples can also aid in diagnosis.
- Treatment regimens are prolonged (a minimum of several months, up to lifelong), and monitoring of serologic and radiologic responses as well as antifungal drug levels are necessary.

eFigure 37-1 Fibrosing mediastinitis due to histoplasmosis. Frontal chest radiograph (A) in a patient with fibrosing mediastinitis shows linear and reticular abnormalities in the right perihilar region and right lower lobe and a small right pleural effusion. Chest CT shown in soft tissue windows (B and C) demonstrates calcified mediastinal lymphadenopathy and noncalcified right peribronchial tissue (arrows). Note that the peribronchial tissue compresses and narrows adjacent vascular structures. A small right pleural effusion is present. Chest CT shown in lung tissue windows (D) reveals right lung smooth interlobular septal thickening (arrowheads), which accounts for much of the linear abnormality apparent on chest radiography. Ventilation (E) and perfusion (F) scintigraphy in the anterior projection shows mildly decreased ventilation in the right lower lung (E), but absent perfusion in the same region on the perfusion images (F). Left lung perfusion is normal. Catheter pulmonary angiography (G) confirms absent perfusion in the right lower lung (area between arrows is right lower lobe lung parenchyma without demonstrable pulmonary blood flow) due to arterial compression, confirming the findings seen on CT (B and C). DEMATIACEOUS (MELANIZED) FUNGI**INTRODUCTION**

The epidemiology of opportunistic mycoses is evolving. In certain populations, the frequency of opportunistic mycoses is increasing due to use of immune-modulating therapies, a higher frequency of invasive procedures and devices, and changes in climate and regional environments. In other populations, the frequency of opportunistic mycoses is decreasing, due to antifungal prophylaxis in high-risk patients and reconstitution of immunity with antiretroviral therapy for *human immunodeficiency virus* (HIV) infection. Heightened clinical awareness of fungal infections and the availability of improved diagnostics contribute to their increased recognition, and the availability of newer antifungal drugs provides broader therapeutic options.

Fungi are eukaryotic microorganisms that grow as yeasts or molds. Endemic fungi such as *Blastomyces dermatitidis* and *Histoplasma capsulatum*, reviewed in the preceding chapter, are considered dimorphic fungi, growing as molds at room temperature and yeast or yeastlike forms at body temperature. Yeasts are unicellular fungi and exist as single rounded or elongated cells and reproduce primarily by budding. The primary opportunistic yeasts reviewed here are *Candida* and *Cryptococcus*. In contrast, molds are multicellular filamentous fungi composed of hyphae that grow by branching with extension at the hyphal apices. Clinically relevant opportunistic molds are often categorized on the basis of their hyphae. Septate hyphae contain cross walls that divide the hyphae into compartments, whereas aseptate or sparsely septate hyphae either lack or infrequently demonstrate these cross walls, respectively. This distinction can be used in identifying molds in respiratory samples and tissue histopathology. Aseptate (or sparsely septate) hyphae are seen in mucormycosis, caused by molds such as *Mucor* and *Rhizopus* (historically referred to as *Zygomycetes*). Opportunistic molds producing septate hyphae are further subdivided as hyaline or dematiaceous molds. Hyaline molds produce colorless or lightly pigmented hyphae in tissue and infections are referred to *hyalohyphomycosis*.

Dematiaceous or black molds are septate molds that contain melanin in their cell walls, resulting in brown pigmentation, which can be seen in histopathology specimens and under direct microscopic examination. Infections with the dematiaceous molds are referred to as *phaeohyphomycoses*.

This chapter discusses the most common opportunistic mycoses of the respiratory tract and their epidemiology, clinical characteristics, diagnosis, and treatment. The chapter begins with discussion of the currently available antifungal agents.

ANTIFUNGAL THERAPY

Rapid initiation of antifungal therapy is essential in the management of *invasive fungal infections* (IFIs). The primary classes of antifungal agents target either the plasma membrane or the cell wall. *Amphotericin B* (AmB) was previously the primary antifungal agent for IFIs; however, newer antifungals, including the extended spectrum azoles and echinocandins, have broadened the therapeutic options, and lipid formulations of AmB have less toxicity. In addition, combination therapy should be considered in certain IFIs. The following section is a broad overview of the major antifungal agents. [Tables 38-1](#) and [38-2](#) summarize details of the available agents including their spectrum of activity, primary toxicities, interactions, recommendations for therapeutic drug monitoring, and the U.S. *Food and Drug Administration* (FDA) approved indications.

POLYENES

The polyenes were the first antifungals in clinical use and include nystatin and AmB. AmB binds to ergosterol, an essential component of the fungal cell membrane. AmB binding increases membrane permeability and causes fungal cell death.¹ AmB also induces proinflammatory cytokines by activating Toll-like receptor 2, which contributes

Table 38-1 Comparison of Antifungal Agents

Antifungal Therapy	Fungal Spectrum of Activity ^{1,5,13,294-308}	Therapeutic Drug Monitoring ^{5,11,309-312}	*Major Adverse Effects ^{1,5,295-308}	*Major Drug Interactions ^{1,5,295-308}
POLYENES				
Amphotericin B deoxycholate (AmB-d, Fungizone)	<i>Aspergillus</i> (resistance in <i>A. terreus</i> , reduced susceptibility in others including <i>A. nidulans</i> , <i>A. ustus</i>)	TDM not recommended	Normocytic, normochromic anemia, hypokalemia, hypomagnesemia	Close monitoring when used with other nephrotoxic therapies
Lipid formulations of AmB:	<i>Candida</i> (resistance in <i>C. lusitanae</i>)		Infusion-related reactions (e.g., chills/rigors, fever, nausea, vomiting; can be reduced with preinfusion acetaminophen and diphenhydramine; meperidine may be used for rigors)	
Liposomal AmB (LAmB, AmBisome)	<i>Cryptococcus</i>		Nephrotoxicity (can be reduced with hydration, often 500 mL normal saline given before and after infusion)	
AmB Lipid Complex (ABLC, Abelcet)	Dematiaceous molds (e.g., <i>Alternaria</i> , <i>Bipolaris</i> , <i>Cladophialophora</i> , <i>Exserohilum</i> , <i>Rhinocladiella</i>)		Nephrotoxicity may be reduced with the lipid formulations of AmB	
AmB Colloidal Dispersion (ABCD, Amphotec)	Endemic fungi (e.g., blastomycosis, coccidioidomycosis, histoplasmosis, paracoccidioidomycosis, <i>Penicillium marneffeii</i> , Sporotrichosis)			
	Mucormycosis (e.g., <i>Rhizopus</i> , <i>Rhizomucor</i> , <i>Mucor</i>)			
	Non- <i>Aspergillus</i> hyaline molds (resistance in some species including <i>Fusarium</i> and <i>Scedosporium</i> , also <i>Purpureocillium lilacinum</i>)			
AZOLES				
Fluconazole (FLU, Diflucan)	<i>Candida</i> (intrinsic resistance with <i>C. krusei</i> , variable susceptibility to <i>C. glabrata</i>) <i>Cryptococcus</i> Some activity against endemic mycoses (e.g., coccidioidomycosis)	TDM not recommended Renal dose adjustment is required	Alopecia (with prolonged therapy) GI effects (diarrhea, nausea, vomiting) Cardiac effects (has been associated with QT prolongation and torsades de pointes in patients with other risks) Hepatotoxicity	Fluconazole is a potent CYP2C9 inhibitor and moderate CYP3A4 inhibitor May interact with drugs metabolized through these enzyme systems Drugs that reduce FLU concentration: rifampin, rifabutin FLU increases concentration of carbamazepine, phenytoin, midazolam, rifabutin, sirolimus, some NSAIDs, tacrolimus, vinca alkaloids, zidovudine Other considerations: –QT prolongation with astemizole, haloperidol, macrolides –Potentiation of warfarin –CNS side effects with all-trans retinoic acid –Increased risk of rhabdomyolysis with atorvastatin, fluvastatin, simvastatin

Table 38-1 Comparison of Antifungal Agents (Continued)

Antifungal Therapy	Fungal Spectrum of Activity ^{1, 5, 13, 294-308}	Therapeutic Drug Monitoring ^{5, 11, 309-312}	*Major Adverse Effects ^{1, 5, 295-308}	*Major Drug Interactions ^{1, 5, 295-308}
Itraconazole (ITRA, Sporanox)	<i>Aspergillus</i> (resistance in some isolates) <i>Candida</i> (including <i>C. krusei</i> , <i>C. glabrata</i> , and <i>C. tropicalis</i>) <i>Cryptococcus</i> Dematiaceous molds Endemic mycoses (including paracoccidioidomycosis) <i>Penicillium marneffei</i> <i>Sporothrix schenckii</i> Trichophyton ITRA is not usually active against mucormycosis or many <i>Fusarium</i> and <i>Scedosporium</i> spp	TDM is recommended Random concentration measured after ≥ 2 weeks of therapy with goal $\geq 1 \mu\text{g/mL}$ For HPLC, the goal concentration is sum of ITRA and active metabolite, hydroxy-ITRA Capsules: take with food and acidic beverage (e.g., cola); avoid proton pump-inhibitors and H ₂ blockers, which decrease absorption Solution: take on empty stomach Blood concentrations $\sim 30\%$ higher with ITRA solution vs. ITRA capsule formulation	Adrenal insufficiency (long-term use, rare) CHF (avoid in patients with ventricular dysfunction or history of CHF) GI effects (diarrhea, nausea, vomiting) Headache Hearing loss Hepatotoxicity Neuropathy Peripheral edema QT prolongation and torsades de pointes in patients with multiple risks Rash	ITRA is a potent CYP3A4 inhibitor and substrate of CYP3A4; may interact with drugs metabolized through this enzyme system Drugs that decrease ITRA concentration: carbamazepine, nevirapine, phenytoin, rifabutin, rifampin Drugs that increase ITRA concentration: macrolide antibiotics, protease inhibitors ITRA increases concentration of busulfan, cyclosporine, carbamazepine, digoxin, dihydropyridines, midazolam, rifabutin, ritonavir, sirolimus, tacrolimus, vinca alkaloids Other considerations: –QT prolongation with dofetilide, pimozone, quinidine –Increased risk of rhabdomyolysis with atorvastatin, fluvastatin, simvastatin
Posaconazole (POSA, Noxafil)	<i>Aspergillus</i> <i>Candida</i> <i>Cryptococcus</i> Endemic fungi, limited data (blastomycosis, coccidioidomycosis, cryptococcosis, histoplasmosis) Non- <i>Aspergillus</i> hyaline molds (species-dependent, limited data) Mucormycosis Dematiaceous molds	TDM is recommended when POSA used for prophylaxis and treatment of systemic infections. Recommendations apply to POSA suspension. See text regarding extended-release tablet and intravenous formulation. Trough concentrations measured \geq day 8 of therapy with goal concentration $\geq 0.7 \mu\text{g/mL}$ In patients not responding to treatment, consider troughs > 1 to $1.25 \mu\text{g/mL}$ Administer with high-fat meal, acidic beverage (e.g., cola, ginger ale) and avoid proton pump inhibitors Note that dose escalation beyond 800 mg/day is unlikely to result in higher concentration as absorption is saturable; increased concentration is best achieved with more frequent dosing intervals (e.g., 400 mg twice daily should be changed to 200 mg by mouth four times daily) Does not require renal dose adjustment	GI effects (diarrhea, nausea, vomiting) Headache Hepatotoxicity QT prolongation (less common than with ITRA or VORI)	POSA is an inhibitor of CYP3A4 and substrate of P-glycoprotein; may interact with drugs metabolized via these systems Drugs that decrease POSA concentration: cimetidine, efavirenz, esomeprazole, phenytoin, rifabutin POSA increases concentration of atazanavir, cyclosporine, digoxin, dihydropyridines, midazolam, rifabutin, ritonavir, sirolimus, tacrolimus, vinca alkaloids Other considerations: –QT prolongation with pimozone, quinidine –Increased risk of rhabdomyolysis with atorvastatin, lovastatin, simvastatin –Avoid use with ergot alkaloids

OTHER				
Flucytosine (5-FC, Ancobon)	<i>Aspergillus</i> <i>Candida</i> <i>Cryptococcus</i> Dematiaceous fungi (some, including <i>Phialophora</i> and <i>Cladosporium</i> spp) <i>Sporothrix schenckii</i> (variable MICs) 5-FC is used in combination therapy, typically with AmB	Cryptococcal infection: concentration measured on day 3 to 5 of therapy, 2 hours after dose, target: 30 to 80 µg/mL When TDM not available both renal function and cell counts must be closely monitored Renal dose adjustment is required	Bone marrow suppression GI effects (abdominal pain, diarrhea, nausea, vomiting) Hepatotoxicity Nephrotoxicity	Aluminum hydroxide or magnesium hydroxide suspension (delays 5-FC absorption) Cytarabine (cytosine arabinoside, competitive inhibitor of 5-FC) Close monitoring when used with other nephrotoxic and myelosuppressive therapies
Terbinafine (TBF, Lamisil)	<i>Aspergillus</i> Sporotrichosis Some activity (usually in combination therapy) against non- <i>Aspergillus</i> hyaline molds (species dependent), dematiaceous molds (species dependent)	TDM not recommended Clearance is decreased by 50% when CrCl ≤ 50 mL/min	Depressive symptoms Hepatotoxicity Neutropenia Rash Smell and taste disturbances	TBF is an inhibitor of CYP2D6 May interact with drugs metabolized via this system, including tricyclic antidepressants, selective serotonin reuptake inhibitors, beta blockers, antiarrhythmic class 1C (e.g., flecainide, propafenone) Drugs that decrease TBF: rifampin Drugs that increase TBF: fluconazole TBF may decrease cyclosporine concentration

*This is not an all-inclusive list of adverse effects and/or drug interactions. Some of the listed drug interactions are considered contraindications to concomitant therapy.

ABCD, amphotericin B colloidal dispersion; ABLC, amphotericin B lipid complex; AmB, amphotericin B; AmB-d, amphotericin B deoxycholate; ANI, anidulafungin; CAS, caspofungin; CHF, congestive heart failure; CNS, central nervous system; CrCl, creatinine clearance; CYP, cytochrome P-450 enzyme system; FLU, fluconazole; GI, gastrointestinal; H2, histamine-2 receptor; ITRA, itraconazole; IV, intravenous; MIC, minimal inhibitory concentration; MICA, micafungin; LAmB, liposomal amphotericin B; NSAIDs, nonsteroidal antiinflammatory drugs; POSA, posaconazole; spp, species; TBF, terbinafine; TDM, therapeutic drug monitoring; VORI, voriconazole; 5-FC, flucytosine.

Table 38-2 FDA Approved Fungal Indications for Specific Antifungal Agents

Antifungal Agent	FDA Approved Indications ^{266, 296-308}
POLYENES	
Amphotericin B deoxycholate (Fungizone), Apothecon Generic available (U.S.): yes	Treatment of potentially life-threatening fungal infections: Aspergillosis Blastomycosis Candidiasis, systemic Coccidioidomycosis Cryptococcosis Histoplasmosis Mucormycosis (including susceptible species of the genera <i>Abidia</i> , <i>Mucor</i> , and <i>Rhizopus</i> and infections due to related susceptible species of <i>Conidiobolus</i> and <i>Basidiobolus</i>) Sporotrichosis
Amphotericin B lipid complex, ABLC (Abelcet), Sigma-Tau Pharmaceuticals Generic available (U.S.): no	Treatment of invasive fungal infections in patients who are refractory or intolerant of conventional amphotericin B therapy
AmB Colloidal Dispersion, ABCD (Amphotec), Alkopharma Generic available (U.S.): no	Treatment of invasive aspergillosis in patients with renal impairment or who are refractory or intolerant of conventional amphotericin B therapy
Liposomal amphotericin B (AmBisome), Astellas Pharma US Generic available (U.S.): no	Treatment of: Aspergillosis and candidiasis (in patients with renal impairment or who are refractory or intolerant of conventional amphotericin B therapy) Cryptococcosis (in HIV patients with cryptococcal meningitis and for cryptococcal infections in patients with renal impairment or who are refractory or intolerant of conventional amphotericin B therapy) Empirical therapy for presumed fungal infection in febrile neutropenic patients

Table 38-2 FDA Approved Fungal Indications for Specific Antifungal Agents (Continued)

Antifungal Agent	FDA Approved Indications ^{266,296-308}
AZOLES	
Fluconazole (Diflucan), Pfizer Generic available (U.S.): yes	Treatment of: Candidiasis (including chronic mucocutaneous candidiasis, esophageal and oropharyngeal candidiasis, <i>Candida</i> urinary tract infection and peritonitis, other systemic <i>Candida</i> infections including candidemia, disseminated candidiasis and pneumonia, vaginal candidiasis) Cryptococcal meningitis Prophylaxis for patients undergoing HSCT who receive cytotoxic chemotherapy and/or radiation therapy
Itraconazole (Sporanox), Janssen Pharmaceuticals Generic available (U.S.): yes	Treatment of: Aspergillosis (pulmonary and extrapulmonary in patients who are intolerant or refractory to amphotericin B) Blastomycosis (pulmonary and extrapulmonary infection) Histoplasmosis (chronic pulmonary disease and disseminated nonmeningeal infection) Onychomycosis of the fingernails and toenails due to dermatophytes (non-immunocompromised only)
Posaconazole (Noxafil), Merck & Co., Inc. Generic available (U.S.): no	Treatment of oropharyngeal candidiasis including that which is refractory to itraconazole and/or fluconazole Prophylaxis of invasive aspergillosis and invasive candidiasis (in severely immunocompromised patients such as HSCT recipients with GVHD or those with hematologic malignancies with prolonged neutropenia from chemotherapy)
Voriconazole (VFEND), Pfizer Generic available (U.S.): yes	Treatment of: Aspergillosis (invasive) Candidiasis (esophageal candidiasis, candidemia in nonneutropenic patients and the following <i>Candida</i> infections: disseminated infections in skin and infections in abdomen, kidney, bladder wall, and wounds) Serious infections caused by <i>Scedosporium apiospermum</i> and <i>Fusarium</i> species, including <i>Fusarium solani</i> , in patients intolerant of, or refractory to, other therapy
ECHINOCANDINS	
Caspofungin (Cancidas), Merck & Co., Inc Generic available (U.S.): no (approval pending)	Treatment of: Aspergillosis (invasive disease in patients who are refractory to or intolerant of other therapies such as amphotericin B, lipid formulations of amphotericin B or itraconazole). Candidiasis (esophageal candidiasis, candidemia, and the following <i>Candida</i> infections: intra-abdominal abscesses, peritonitis, and pleural space infections) Empirical therapy for presumed fungal infections in febrile neutropenic patients
Micafungin (Mycamine), Astellas Pharma US Generic available (U.S.): no	Treatment of candidiasis (esophageal candidiasis, candidemia, acute disseminated candidiasis, peritonitis, and abscesses) Prophylaxis of <i>Candida</i> infections in patients undergoing HSCT
Anidulafungin (Eraxis), Pfizer Generic available (U.S.): no	Treatment of candidiasis (esophageal candidiasis, candidemia, and other forms of <i>Candida</i> infections including intra-abdominal abscess and peritonitis)
OTHER	
Flucytosine (Ancobon), Valeant Pharmaceuticals Generic available (U.S.): yes	Treatment of: Candidiasis (susceptible strains causing septicemia, endocarditis, urinary tract infections, and pneumonia) Cryptococcosis (susceptible strains causing meningitis, pulmonary infections, septicemia, and urinary tract infections) Note that flucytosine should be used in combination with amphotericin B for the treatment of systemic candidiasis and cryptococcosis because of the emergence of resistance to flucytosine monotherapy
Terbinafine (Lamisil), Novartis Generic available (U.S.): yes, product dependent	Treatment of onychomycosis of the toenail or fingernail due to dermatophytes

GVHD, graft-versus-host disease; HSCT, hematopoietic stem cell transplant; U.S., United States.

to the acute side effects of fever and myalgias, and may augment host responses to fungal infection.² AmB has activity against multiple fungal pathogens including *Aspergillus*, *Candida*, the endemic mycoses (e.g., blastomycosis, coccidioidomycosis, cryptococcosis, histoplasmosis) and mucormycosis.³ However, certain fungi, including *Aspergillus terreus*, *Candida lusitanae*, *Scedosporium prolificans*, and *Trichosporon beigelii*, may be intrinsically resistant to AmB, and other pathogens such as *Fusarium* species and the dematiaceous molds may have high *minimal inhibitory concentrations* (MICs) to AmB.⁴

The lipid formulations of AmB were introduced to reduce nephrotoxicity seen with conventional amphotericin, termed *amphotericin B desoxycholate* (AmB-d). The lipid formulations of AmB are now often used first-line, particularly in patients with renal dysfunction or on concurrent nephrotoxic medications. Lipid formulations include *liposomal AmB* (LAmB) and *AmB lipid complex* (ABLC). Due to its ten- to sixty-fold lower cost compared with the lipid formulations, conventional AmB-d continues to have an important role in treatment of patients at low risk of toxicity, such as outpatients without comorbidities.

AZOLES

Certain drugs containing an imidazole ring have antimicrobial activity. N-substituted azoles, termed triazoles, have antifungal activity and acceptable host toxicity, and have emerged as a primary class of antifungals for treatment and prevention of IFIs. For the purpose of brevity, the antifungal triazoles are commonly termed *azoles*, as they are in this chapter. The most widely used azoles are fluconazole, itraconazole, posaconazole, and voriconazole. These agents act on the fungal cell membrane by inhibiting the cytochrome P-450–dependent 14- α -demethylase, a critical enzyme in the conversion of lanosterol to ergosterol. The azoles are fungistatic or fungicidal, depending on the specific azole and fungal species.⁵ Immunomodulating effects have been described with azoles and may contribute to their efficacy.² While earlier azoles, such as fluconazole, are active against yeasts, the expanded spectrum azoles, including voriconazole and posaconazole, are active against yeasts and molds. Fluconazole is active against *Cryptococcus* and *Candida*, and has variable activity against endemic fungi, including *Coccidioides*. *Candida krusei* is intrinsically resistant to fluconazole and high-level resistance is emerging among some non-*albicans* *Candida* species, including *C. glabrata*. Itraconazole has little role in treatment of opportunistic fungal infections; its principal indications are treatment of indolent, non-central nervous system (CNS) blastomycosis or histoplasmosis, and as an alternative to fluconazole for treatment of indolent non-CNS coccidioidomycosis. Itraconazole is also indicated in treatment of *allergic bronchopulmonary aspergillosis* (ABPA). Itraconazole exhibits highly variable absorption and pharmacokinetics; therapeutic drug monitoring is essential to guide optimal dosing for an individual patient.

The extended-spectrum azoles have activity against many molds, including *Aspergillus*, non-*Aspergillus* hyaline hyphomycetes such as *Fusarium*, *Scedosporium*, and *Paecilomyces*, and some dematiaceous molds. Voriconazole is the drug of choice for the treatment of invasive *Aspergillus* infections. Among the azoles, only posaconazole has activity against the agents of mucormycosis.

ECHINOCANDINS

The echinocandins, including caspofungin, micafungin, and anidulafungin, are increasingly used given their efficacy, tolerability, lack of drug interactions, and the prevalence of azole-resistant *Candida* species. Unlike AmB and the azoles, the echinocandins act on the fungal cell wall via inhibition of (1 \rightarrow 3)- β -D-glucan synthase, thereby inhibiting production of (1 \rightarrow 3)- β -D-glucan (β -D-glucan), an essential component of the fungal cell wall. Echinocandins are fungicidal against multiple *Candida* species, including *C. albicans*, *C. dubliniensis*, *C. glabrata*, and *C. krusei*; however, certain *Candida* species, such as *C. guilliermondii* and *C. parapsilosis*, typically have higher MICs. The echinocandins are fungistatic rather than fungicidal against filamentous fungi such as *Aspergillus* species because their activity is restricted to sites where the fungal cell wall is actively growing (i.e., hyphal tips and branching junctional cells), and are not active on subapical hyphal cells.⁶ Echinocandins lack significant activity against other fungal pathogens

such as *Cryptococcus*, *Mucorales*, and *Trichosporon* species and the endemic fungi.⁷ The immunostimulatory effects of echinocandins on monocytes and monocyte-derived macrophages may be of particular importance against *Aspergillus*.^{8,9}

FLUCYTOSINE

Flucytosine is an antimetabolite that inhibits fungal DNA and protein synthesis. It is used in combination with other antifungal agents given the high frequency of emergence of resistance with monotherapy.¹⁰ It is fungistatic or fungicidal, depending upon the organism, and is most often used in combination with AmB against *Cryptococcus*¹¹ and in severe *Candida* infections such as endocarditis and CNS infections.¹²

TERBINAFINE

Terbinafine is a synthetic allylamine that exerts its antifungal effects via inhibition of fungal squalene epoxidase, an enzyme involved in ergosterol formation. Terbinafine is fungicidal and is used most commonly for dermatophyte infections and the treatment of chromoblastomycosis.¹³ In vitro synergy data have led to its use in combination, most often with extended-spectrum azoles and AmB, for the management of severe or refractory mold infections such as *Scedosporium*,¹⁴ *Fusarium*,¹⁵ and other hyaline and dematiaceous molds.¹³

CRYPTOCOCCOSIS

EPIDEMIOLOGY

Cryptococcus neoformans has a global distribution and can be isolated from the soil and excreta of birds such as pigeons. *C. neoformans* var. *grubii* (serotype A) is the predominant pathogen worldwide; however, infections with *C. neoformans* var. *neoformans* (serotype D) are prevalent in Northern Europe. *C. gattii* can cause disease in immunocompetent patients. Until recently, *C. gattii* was found in Australia, Southeast Asia, and Central Africa, often associated with eucalyptus and fir trees. Recently, serious infections with *C. gattii* have been recognized in Vancouver, British Columbia, and in the Pacific Northwest United States.^{16,17} Most cryptococcal infections are seen in immunocompromised hosts, including patients with advanced HIV infection,¹⁸ malignancies,¹⁹ *solid organ transplants* (SOT),²⁰ and other conditions.²¹

Cryptococcosis is one of the most common life-threatening fungal infections in HIV-infected patients,²² and is the third most common invasive fungal pathogen (behind *Candida* and *Aspergillus*) in SOT recipients in whom it causes 8% of IFIs.²³ *Cryptococcus* affects *hematopoietic stem cell transplant* (HSCT) patients less often, in whom it causes 0.6% of IFIs.²⁴

PATHOGENESIS

Infections with *Cryptococcus* are initiated by inhalation of small yeast or spores (produced through mating). Once in the alveoli, the outcome is determined by the virulence of

the infecting strain, by host genetic polymorphisms, by innate and adaptive immune responses, and by the presence of comorbidities. The virulence of *Cryptococcus* is related to its polysaccharide capsule as well as the presence of specific enzymes including laccase (required for production of fungal melanin), phospholipase B, and inositol phosphosphingolipid-phospholipase.²⁵ In the lungs, cryptococci replicate and synthesize a large polysaccharide capsule, which protects against phagocytosis. The cryptococci that are successfully phagocytosed reside and replicate in mature phagolysosomes and subsequently spread to other cells using multiple mechanisms.²⁶

Cryptococci encounter diverse elements of the innate immune response, including polymorphonuclear cells, macrophages, and dendritic cells, which produce the cytokines that drive a type 1 helper CD4⁺ T cell response.²⁷ CD4⁺ cells are necessary to prevent dissemination from the lungs; both CD4⁺ and CD8⁺ cells are required for clearance of infection in mice.²⁸ Defects in humoral immunity are less commonly associated with cryptococcal infections than are defects in cellular immunity,²⁹ although antibody-mediated immunity contributes to control of cryptococci in mice.^{27,30} The presence of autoantibodies to granulocyte macrophage colony stimulating factors may predispose seemingly immunocompetent individuals to infection with *C. gattii*.

CLINICAL MANIFESTATIONS

The clinical presentation of cryptococcal infections is determined by the immune status of the host, the *Cryptococcus* species, and the site of infection. The lungs are the most commonly involved primary site; the CNS is the most common site of dissemination. Pulmonary involvement ranges from asymptomatic colonization to multifocal consolidation and acute respiratory distress syndrome. Most pulmonary infections are asymptomatic or mildly symptomatic in immunocompetent hosts, and may be discovered incidentally on radiographic imaging. *Cryptococcus* is also believed to cause latent infection in the lung and reactivate in the setting of depressed immunity. In fact, most infections may represent reactivation, and transfer of infection

with donor organs may contribute to risk in SOT patients.³¹ Dissemination may develop during primary infection or reactivation. Acute infection in the immunocompetent host may manifest with fever, fatigue, cough, and sputum production. In immunocompromised patients, severe symptoms, including fever, cough, and shortness of breath, can rapidly progress to respiratory failure and acute respiratory distress syndrome. In a prospective multicenter international study of 111 SOT recipients, cryptococcal infections typically were seen a median of 21 months after transplant, and pulmonary (60%) and CNS (58%) involvement were most common.³² In patients with advanced HIV infection, meningoencephalitis is the predominant presentation.³³

The radiographic findings in cryptococcal pulmonary infections commonly include focal or diffuse pulmonary nodules or patchy air-space consolidation (eFig. 38-1). However, other findings include cavitation (see eFig. 90-24), mass lesions (i.e., cryptococcomas, (see eFigs. 90-23 and 90-24), reticulonodular patterns, ground-glass attenuation (see eFig. 90-21), and associated effusions or lymphadenopathy (see eFig. 90-24A and B).^{34,35} In a study of computed tomography (CT) radiographic findings of cryptococcosis, immunocompromised patients had more extensive pulmonary involvement with cavitation and parenchymal consolidation than did immunocompetent hosts—a finding that contrasts with that in tuberculosis.³⁴ Cryptococcomas in both the CNS and in the lungs are seen more commonly with *C. gattii* than with *C. neoformans* infection, and are more common in immunocompetent hosts.³⁶

DIAGNOSIS

The diagnosis of pulmonary cryptococcosis is based on symptoms, chest radiography, culture, and/or histopathologic findings (Fig. 38-1) and cryptococcal antigen testing. *Cryptococcus* can be cultured from respiratory specimens including sputum and bronchoalveolar lavage (BAL); blood cultures are only positive in disseminated infections. *Cryptococcus* is easily identified under the microscope as 5 to 10 μ m spherical to oval yeast cells with a surrounding

Figure 38-1 Cryptococcus. Pulmonary infection with *Cryptococcus* in an asymptomatic cardiac transplant patient on chronic immunosuppression with new, bilateral pulmonary nodules. **A**, Axial chest CT demonstrates a cavitary nodule (arrow) with small surrounding satellite nodules. **B**, CT-guided fine-needle aspiration of the pulmonary nodule shows encapsulated yeast (arrows), with the typical morphology of *Cryptococcus neoformans* (Papanicolaou stain; original magnification $\times 400$). Inset: Yeast showing mucin capsule with organism staining positive. (Methenamine silver stain; original magnification $\times 400$). (B, Courtesy Dr. Thomas Sporn, Duke University Medical Center, NC.)

capsule. Biochemical testing is used to confirm the identification; canavanine-glycine-bromothymol blue agar can be used for differentiating *C. gattii* from *C. neoformans*.³⁷ New methods are under development for rapid identification and speciation of cryptococci, including *polymerase chain reaction* (PCR)³⁸ and matrix-assisted laser desorption/ionization time of flight spectrometry.³⁹

In tissue samples, specialized stains such as Mayer's mucicarmine, which stains fungal melanin, are also helpful in establishing a diagnosis.³⁷ While the serum cryptococcal antigen assay has a high sensitivity and specificity in disseminated infection and cryptococcal meningoencephalitis, it can be negative in patients with isolated pulmonary infection. In a study of patients with SOT, serum cryptococcal antigen was detectable in 73% of patients (22 of 30) with isolated pulmonary involvement and was more likely to be negative with solitary pulmonary nodules than with multiple nodules and more extensive pulmonary disease. Titers of serum cryptococcal antigen were higher in those patients with concurrent extrapulmonary infection.⁴⁰

Determining the presence of disseminated infection and extent of organ involvement is crucial to the selection of appropriate therapy. Thus, cerebrospinal fluid evaluation (e.g., cell count, culture, and cryptococcal antigen) should be performed in all immunosuppressed patients with pulmonary cryptococcosis. Whether cerebrospinal fluid analysis is essential in immunocompetent patients with pulmonary cryptococcosis is less clear. Factors associated with higher likelihood of disseminated disease and the need for cerebrospinal fluid analysis include neurologic findings, signs of systemic infection, such as fever and weight loss, and serum cryptococcal Ag titer of at least 64.⁴¹

TREATMENT

The choice of therapy depends on the immune status of the host and the presence of extrapulmonary infection; current treatment recommendations are available from both the American Thoracic Society⁴² and *Infectious Diseases Society of America* (IDSA).¹¹ For pulmonary cryptococcosis in patients with evidence of disseminated infection, CNS involvement, or severe pneumonia, the treatment is separated into induction, consolidation, and maintenance regimens. The antimicrobials, doses, and duration are dependent on the patient's underlying risk group (e.g., HIV-infected, organ transplant recipient, and non-HIV infected, non-transplant recipient). Induction therapy is typically with AmB-d 0.7 to 1 mg/kg/day plus flucytosine 100 mg/kg/day. In transplant patients and patients with reduced renal function, lipid formulations of AmB (e.g., LAmB 3 to 4 mg/kg/day or ABLC 5 mg/kg/day) are substituted for AmB-d to minimize nephrotoxicity. Fluconazole is utilized for consolidation and maintenance therapy with doses ranging from 400 to 800 mg/day and 200 to 400 mg/day, respectively.¹¹

Mild-to-moderate infection isolated to the lungs is treated with fluconazole 400 mg/day for a minimum of 6 to 12 months. Some experts maintain that asymptomatic patients with resected solitary nodules, undetectable serum cryptococcal antigen, and no evidence of extrapulmonary infection may be observed closely without specific antifungal therapy.¹¹ Infections with *C. gattii* have been associated

with delayed clinical responses to antifungal therapy; potential explanations include high in vitro fluconazole MICs and a higher incidence of pulmonary and cerebral cryptococcomas with decreased drug penetration to these lesions.^{11,43,44}

Immune reconstitution inflammatory syndrome (IRIS) may complicate treatment of any opportunistic mycosis, but is most common in cryptococcosis. IRIS is usually characterized by worsening of clinical signs and symptoms of the original infection, which can be misinterpreted as progressive infection.^{11,45} IRIS arises most commonly with initiation of potent antiretroviral therapy in HIV infection and with abrupt improvement in immune competence in SOT recipients. Although less common, IRIS can also happen in patients with hematologic malignancies during neutrophil and monocyte recovery following myeloablative chemotherapy⁴⁶ and with lymphocyte recovery after receipt of monoclonal antibodies such as alemtuzumab.⁴⁷ The manifestations of IRIS in pulmonary disease may be severe and include acute respiratory distress syndrome. Transplant recipients developing IRIS associated with cryptococcal infection also have increased potential for allograft loss.⁴⁸ Treatment of IRIS in transplant recipients includes adjustment of immunosuppressive drugs to moderate the symptoms without promoting progression of the infection.¹¹ Nonsteroidal antiinflammatory drugs are often sufficient to ameliorate the symptoms of IRIS, but high-dose corticosteroids may be required to manage the complications of severe IRIS.

CANDIDIASIS

The epidemiology of invasive *Candida* infections has evolved substantially in the past 2 decades.^{49,50} While *Candida albicans* remains the most common species associated with invasive disease overall, more than 17 *Candida* species have been associated with human disease⁵¹ and non-*albicans* species account for an increasing proportion of infections.^{12,49,52}

Candida infections of the thorax include empyema, tracheobronchial and mediastinal infection, and pneumonia. *Candida* pneumonia is rare and is most often found in the setting of candidemia with dissemination to the lung in immunocompromised patients.^{53,54} Rarely, primary pneumonia develops due to aspiration of oropharyngeal contents.^{53,55,56} Mediastinitis may complicate thoracic surgical procedures, and tracheobronchial disease can follow lung transplantation.^{57,58} *Candida* species have multiple virulence determinants; virulent strains consistently exhibit adherence to devices and tissues and form biofilms.⁵¹ Multiple human genetic polymorphisms have been identified that contribute heightened susceptibility to mucosal and invasive *Candida* infections. These include common and rare sequence variants in Toll-like receptors 1, 2, and 4, cytokine signaling (*interleukin* [IL]-10, and the shared subunit of IL-12 and IL-23 receptors), and multiple genes whose products contribute to generating or responding to IL-17.⁵⁹

Manifestations of *Candida* pneumonia include cough, dyspnea, and fever. Radiographic findings are variable and can include lobar (eFig. 38-2) and multilobar consolidation as well as cavitation.⁵⁴ The diagnosis of *Candida* pneumonia

is complicated by the generally low specificity and low positive predictive value of isolating *Candida* in respiratory specimens, which is often interpreted as colonization.^{53,54,60,61} Consequently, histopathologic evidence of tissue invasion is required to prove *Candida* pneumonia. Detection of the fungal cell wall component β -D-glucan in serum may assist in distinguishing colonization from invasive *Candida* infection. In patients with hematologic malignancy and in critically ill patients, detection of β -D-glucan has been shown to result in earlier diagnosis of candidemia and invasive candidiasis,^{62,63} although the specificity of this test is limited by multiple sources for false-positive tests and cross-reactivity due to synthesis of β -D-glucan by other fungi, and low positive predictive value. Molecular methods such as real-time PCR testing of blood for invasive candidiasis are under development but are not yet available for clinical use.^{64,65}

Given the increasing number of infections with non-*albicans* *Candida* species and the potential for infection with azole-resistant strains, echinocandins or lipid AmB preparations are preferred for initial therapy while awaiting species identification and susceptibility testing. Whereas the extended spectrum azoles such as voriconazole may be more active against *C. glabrata* than is fluconazole,⁶⁶ there is frequent cross-resistance among the azoles.⁶⁷⁻⁶⁹ In addition, *C. glabrata* isolates have demonstrated resistance to echinocandins, often with poor outcomes.^{70,71,73,74} *C. lusitanae* is intrinsically resistant to AmB, and *C. tropicalis* has shown increasing acquired resistance to azoles and to echinocandins.^{70-72,75} *C. parapsilosis* and *C. guilliermondii* tend to have higher MICs for the echinocandins than do other species, but the clinical significance is unclear.⁷⁶⁻⁷⁸ These observations emphasize the importance of knowing the local epidemiology and resistance patterns for *Candida* within an institution, identifying the infecting pathogen to the species level and, in non-*albicans* *Candida* infections, testing susceptibility to guide therapeutic decision making. Drainage of infected fluid collections, including those in the mediastinum or pleural space, is critical for cure.

ASPERGILLOSIS

INTRODUCTION AND EPIDEMIOLOGY

Aspergillosis, caused by multiple species of the genus *Aspergillus*, is the most common mold infection worldwide. *Aspergillus* is a ubiquitous saprophytic fungus found indoors and outdoors in association with soil, organic debris, food, and water. The *Aspergillus* conidial head produces large numbers of 2 to 3 μ m conidia (asexual spores), which easily enter the lungs via inhalation. Outbreaks often follow renovation and construction, activities that place a large number of *Aspergillus* conidia in the air. While the lung is the most common site of entry, *Aspergillus* may gain access to the host via other routes, including direct cutaneous inoculation. Among *Aspergillus* species, *A. fumigatus* is the most common pathogen, in part due to specific virulence factors,⁷⁹ but non-*fumigatus* species including *A. flavus*, *A. niger*, and *A. terreus*, also cause human disease.^{23,24,80} *A. terreus* is notable for exhibiting in vitro resistance to AmB.^{81,82} *A. nidulans*, an otherwise rare pathogen, is second to *A. fumigatus* as the

Figure 38-2 Invasive aspergillus. Micrograph shows findings of invasive *Aspergillus* infection represented by septate hyphae with finger-like branching at acute angles. (Methenamine silver stain; original magnification $\times 450$.)

most common mold causing infection in patients with chronic granulomatous disease.⁸³

Aspergillus is a hyaline hyphomycete characterized by septate, narrow (3 to 6 μ m) hyphae with acute angle (45 degrees) branching (Fig. 38-2) in respiratory secretions and tissue specimens. The non-*Aspergillus* hyaline hyphomycetes, discussed later, have a similar appearance in clinical specimens and are differentiated from *Aspergillus* in culture based on the morphologic characteristics of their reproductive structures.

Aspergillosis may present as a skin/soft tissue, ocular, gastrointestinal, cardiac, sinus, CNS, or disseminated infection, but most commonly presents as infection limited to the lung.⁸⁵ The five clinical entities addressed in the following sections include the two noninvasive forms, the saprophytic (aspergilloma) and allergic (ABPA) entities, as well as the three invasive forms, including *invasive pulmonary aspergillosis* (IPA), *tracheobronchial aspergillosis* (TBA), and chronic necrotizing pulmonary aspergillosis.

PATHOGENESIS

Although *Aspergillus* species are not obligate pathogens, their evolution to survive in decomposing organic matter has provided them with mechanisms that contribute to virulence in humans and other mammals. Through genome sequence analysis, studies of deletion mutants, and studies of infection in animal models, several determinants and mechanisms of *Aspergillus* pathogenesis have been identified. *Aspergillus* possesses multiple defenses against reactive oxygen intermediates; some of these anti-reactive oxygen intermediates defenses include melanin, catalases, superoxide dismutases, and glutathione transferases. At the same time, *Aspergillus* is able to survive in hypoxic environments, which may allow the fungus to survive in tissues that it renders hypoxic by invading blood vessel walls. Other mechanisms that may contribute to pathogenesis include production of diverse toxins, including gliotoxin and fumagillin, and secretion of elastase, which may promote tissue invasion.⁸⁸

Work in humans and in murine models has provided considerable insight into the elements and mechanisms of innate and adaptive immune responses that provide protection against invasive *Aspergillus* infections (see Chapters 12

and 13).^{89,90-93} *Aspergillus* spores possess a hydrophobic protein coat made up of rod-shaped structures (rodlets), which mask the cell wall and prevent recognition by innate immune receptors. This allows individuals to inhale millions of fungal spores every day without induction of an inflammatory response. Spores that swell and germinate before being killed expose the fungal cell wall that contains multiple pathogen-associated molecular patterns recognized by innate immune cells. In particular, β -D-glucan is recognized by host dectin-1, which initiates production of proinflammatory cytokines and chemokines, and modulates differentiation of CD4⁺ T cells. The importance of specific pathways of innate immune recognition has been demonstrated by finding that hematopoietic stem cell transplant patients who receive donor cells that possess sequence variants of Toll-like receptor 4 or dectin-1 are at increased risk for invasive *Aspergillus* infections.⁹⁴⁻⁹⁶ The chemokines produced early in infection recruit neutrophils and monocytes, both of which play important roles in ingesting and killing germinating spores and hyphae. Other important elements of innate immunity have been identified by finding that polymorphisms of mannose-binding lectin,^{97,98} chemokine (C-X-C motif) ligand 10 (CXCL-10),⁹⁴ and plasminogen⁹⁵ are associated with increased susceptibility to allergic or invasive aspergillosis in certain populations.

In humans and mice, CD4⁺ T cells also contribute to defense against invasive aspergillosis; both T-helper 1 and 17 cells contribute to optimal immunity. In contrast, excessive T-helper 2 responses contribute to the pathogenesis of ABPA.

INFECTION TYPES

Aspergilloma

Epidemiology and Definitions. An aspergilloma (or fungus ball) develops within a preexisting pulmonary cavity; it is a tangled mass of fungal hyphae, cellular debris, mucus, and fibrin that may or may not adhere to the cavity wall. Aspergillomas were previously most commonly found in cavities caused by tuberculosis,⁹⁹ but aspergillomas develop in other cavities such as those caused by bullous emphysema, fibrocavitary sarcoidosis, lung cancer, *cystic fibrosis* (CF),¹⁰⁰ or other fungal^{101,102} or nonfungal infections.⁸⁶ Aspergillomas are most commonly caused by *A. fumigatus* but can also be seen with non-*fumigatus* *Aspergil-*

lus and other molds.^{87,103-105} Chronic cavitary aspergilloma, also known as chronic cavitary pulmonary aspergillosis, is characterized by multiple cavities with or without intracavitary aspergillomas and with pulmonary and systemic symptoms.⁸⁵ Chronic cavitary pulmonary aspergillosis does not invade the surrounding pulmonary parenchyma.¹⁰⁶

The natural history of aspergillomas is variable. Aspergillomas can remain stable over long periods, regress, spontaneously resolve, or progressively enlarge.¹⁰⁷ Patients with aspergillomas are often asymptomatic, and the lesion may be discovered incidentally on chest radiography. The most common symptoms are cough and hemoptysis. Hemoptysis may develop in up to of 85% of cases and ranges from mild to life-threatening.^{107,108} Proposed mechanisms for the development of hemoptysis include vascular damage by mechanical effects of the fungus ball as well as by fungal toxins.¹⁰⁷

Imaging is key to the diagnosis of aspergillomas, which are typically found in the upper lung fields and classically appear as a solid rounded mass within a cavity (Fig. 38-3). The mass may be mobile (eFig. 38-3) or adherent to the cavity wall; peripheral lesions may be associated with pleural thickening. Nonradiographic diagnostic support includes positive serum precipitating antibodies to *Aspergillus* species, which are detectable in approximately 95% of patients.¹⁰⁵ Respiratory cultures may grow *Aspergillus* species although the sensitivity and specificity are low.^{104,107}

Optimal treatment of aspergillomas depends on the patient's symptoms, the location of the aspergilloma, and the host status. In patients with hemoptysis, the primary curative intervention is surgical resection. However, surgical resection remains a high-risk intervention in those with lung disease and poor pulmonary reserve. Potential complications from surgical resection include persistent hemorrhage, bronchopleural fistula development with further spread of the infection, and death.⁸⁵ Therefore, resection to prevent future complications and disease progression must be approached cautiously.¹⁰⁹ Bronchial artery embolization may be used in the setting of acute bleeding as a temporizing measure in nonsurgical candidates.

Systemic and/or topical (nebulized, or instilled into a cavity) antifungal therapy has been attempted in the management of aspergillomas. Systemic azole therapy is rarely curative and may be used for symptom improvement or stabilization and, in immunocompromised hosts, to prevent dissemination and invasive infection.¹¹⁰ The preponderance

Figure 38-3 Aspergillomas in sarcoidosis cavities. **A**, Frontal chest radiograph in a patient with sarcoidosis demonstrates biapical thin-walled cavities containing rounded intracavitary opacities (arrows) that represent aspergillomas. **B**, Axial chest CT displayed in lung windows performed in another patient with sarcoidosis demonstrates biapical aspergillomas (arrows). The background bronchovascular thickening and subpleural nodularity reflects sarcoidosis. (Modified from Gotway MB, Dawn SK, Caoili EM, et al: The radiologic spectrum of pulmonary *Aspergillus* infections. *J Comput Assist Tomogr* 26:159-173, 2002.)

of data supports use of oral itraconazole. An international open-label study of 42 patients with aspergillomas treated with itraconazole at a dose of 100 to 400 mg per day for 18 to 780 days found symptomatic improvement in 62% of evaluable patients ($n = 34$) and radiographic improvement in 12 (30%).¹¹¹ Although fewer data are available, voriconazole is increasingly used instead of itraconazole.^{110,112,113} Major concerns with long-term azole administration are the emergence of resistance and toxicities,^{114,115} especially with voriconazole, which has been associated with development of skin cancers including squamous cell carcinoma.¹¹⁶ Direct intracavitary instillation of antifungal agents such as AmB, nystatin, natamycin, fluconazole, and itraconazole has been used via endobronchial and percutaneous CT-guided approaches and may further reduce fungal burden and the risk of recurrent bleeding, but it is not curative.¹¹⁷⁻¹¹⁹ The optimal management of aspergillomas remains to be defined, and randomized-controlled trials are lacking.

Allergic Bronchopulmonary Aspergillosis

Epidemiology and Pathogenesis. ABPA (see also Chapter 48), first described in the early 1950s, is an allergic pulmonary disorder caused by hypersensitivity to *Aspergillus* antigens.¹²⁰ It is most often encountered in steroid-dependent asthmatics and in upwards of 15% of patients with CF.¹²¹ ABPA is most commonly associated with *A. fumigatus*; however, non-*fumigatus* *Aspergillus* species as well as non-*Aspergillus* molds can cause a similar clinical presentation (the latter termed *allergic bronchopulmonary mycosis* or ABPM). In ABPA, *Aspergillus* conidia enter the airways, germination ensues, and the hyphae colonize but do not invade. *Aspergillus* contributes to pathogenesis by producing enzymes such as elastase, collagenase, and trypsin, with airway damage and release of inflammatory cytokines.¹⁰⁰ A marked inflammatory response ensues, resulting in mucoid impaction and granulomatous inflammation, including bronchocentric granulomas. The immune mechanisms associated with ABPA include an exaggerated T-helper 2 CD4⁺ T-cell response to *Aspergillus* antigens, increased *Aspergillus*-specific and total IgE, and eosinophilia.^{100,122} The primary determinant of dysregulated immune responses in ABPA has not been identified. ABPA is common in patients with CF, and has been linked to polymorphisms in the *CF transmembrane conductance regulator* (CFTR) and pulmonary surfactant protein-A2 genes.¹⁰⁰

Clinical Presentation and Diagnosis

Symptoms of ABPA include acute attacks of wheezing, sputum expectoration containing brown plugs, pleuritic chest pain, and fever. Radiographic findings include transient pulmonary opacities, particularly in the upper lobes, bronchial wall thickening (ring sign), bronchiectasis (tram tracks), bronchial impaction, creating the so-called finger-in-glove appearance (eFig. 38-4) and, in more advanced stages, fibrosis.¹²³ The clinical criteria proposed for diagnosing ABPA differ based on the patient's underlying disease. The minimal essential clinical criteria proposed by Greenberger et al¹²⁴ for asthmatics include (1) asthma, (2) central bronchiectasis, (3) immediate cutaneous reactivity to *Aspergillus* species, (4) a total serum IgE greater than

1000 IU/mL, and (5) elevated *Aspergillus*-specific serum IgE or IgG. Asthmatics are designated as ABPA-central bronchiectasis or ABPA-seropositive, the latter lacking central bronchiectasis. Five stages of disease have been characterized, including (1) acute ABPA, (2) remission, (3) recurrent exacerbation, (4) steroid-dependent asthma, and (5) fibrosis. In patients with CF, the diagnosis is less straightforward, because frequent infections and CF exacerbations may present with symptoms similar to those of ABPA. However, clinical criteria have been proposed by the Consensus Conference of the Cystic Fibrosis Foundation to aid in the diagnosis: (1) acute or subacute pulmonary deterioration not attributable to another etiology; (2) total serum IgE greater than 500 IU/mL; (3) immediate cutaneous reactivity to *Aspergillus* or specific IgE antibodies to *Aspergillus*; and (4) one of the following: *Aspergillus* serum precipitins, elevated anti-*Aspergillus* IgG, or new or recent chest radiographic or chest CT abnormalities that have not cleared with antibiotics and chest physiotherapy.¹²²

The goal of therapy for ABPA is to manage acute disease and prevent relapse and progression to fibrosis. Corticosteroids remain the basis for therapy although there is a lack of guidance from randomized controlled trials assessing the optimal dose and duration. For acute management, oral prednisone at 0.5 mg/kg/day for 1 to 2 weeks, followed by alternate-day dosing for an additional 6 to 8 weeks with further taper is often used.¹²¹ Serum IgE concentrations, radiographic imaging, pulmonary function testing, and clinical symptoms are used to monitor response to therapy and to identify exacerbations.

Antifungal therapy aimed at reducing overall fungal burden, thereby blunting downstream immunologic response and airway inflammation is often used as an adjunctive intervention. The agent most studied for this indication is itraconazole. A meta-analysis¹²⁵ identified three randomized controlled trials evaluating azoles in ABPA, including two trials with itraconazole.^{126,127} Although the studies used different end points, the collective results demonstrated reductions in systemic and airway inflammatory parameters, reductions in steroid dose, improvements in pulmonary function, and an increase in the length of time between exacerbations. Itraconazole was studied at a dose of 400 mg/day for 16 weeks; in clinical practice, some advocate continuing treatment for a minimum of 6 months.¹²⁸ Efficacy has been demonstrated in patients with CF as well.¹²⁹ Based on existing data, the IDSA recommends combination therapy with corticosteroids and antifungals.⁸⁵ Given concerns for itraconazole tolerability, voriconazole and posaconazole have been substituted with good results.¹³⁰ Additional therapeutic considerations include omalizumab, a humanized monoclonal antibody targeting IgE and approved for the treatment of severe allergic asthma. This agent has been used in asthmatic and CF ABPA patients with mixed results.^{131,132}

Invasive Pulmonary Aspergillosis

Epidemiology and Pathogenesis. IPA is the most severe form of pulmonary aspergillosis and is a major cause of fungal morbidity and mortality, seen most commonly in immunodeficient patients, including HSCT and SOT recipients and those with advanced HIV infection, chronic granulomatous disease, and hematologic malignancies. In

Figure 38-4 Invasive pulmonary aspergillosis. **A**, Axial chest CT displayed in lung windows performed in a hematopoietic stem cell transplant recipient during profound neutropenia demonstrates a poorly defined nodule with surrounding ground-glass opacity (arrows) representing the “halo sign.” **B**, Following engraftment, the nodule has become cavitary (arrowheads), representing the “air-crescent” sign.

a retrospective Italian cohort of nearly 12,000 patients with hematologic malignancies, more than half of the 538 proven or probable IFIs were due to molds, primarily *Aspergillus*, and patients with acute myelogenous leukemia were most commonly affected.¹³³ The elevated risk in this population is primarily driven by prolonged neutropenia induced by cytotoxic chemotherapy.¹³⁴ Multicenter, prospectively obtained epidemiologic data also confirm *Aspergillus* as the most common cause of invasive mold infection in both HSCT and SOT recipients.^{23,24} In HSCT recipients, *Aspergillus* is the most common IFI, predominantly seen during two periods: (1) early after transplantation, during neutropenia, and (2) after engraftment, in the setting of graft-versus-host disease. Of the SOT patients, lung transplant recipients are at highest risk for IPA. IPA is also increasingly reported in patients previously thought to be at low risk for invasive disease, including those with COPD on long-term corticosteroids and critically ill patients in the intensive care unit.¹³⁵

IPA is characterized by tissue invasion, frequently involving blood vessels. Hyphae within the alveoli penetrate the respiratory mucosa and alveolar capillaries into endothelial cells and pulmonary arterioles. Cell injury and inflammation contribute to intravascular thrombosis, local hypoxia, and necrosis. Angioinvasive disease is accompanied by tissue infarction and coagulative necrosis, whereas nonangioinvasive disease is more commonly associated with pyogranulomatous inflammation and inflammatory necrosis.¹⁰⁶

Clinical Presentation and Diagnosis. The clinical presentation of IPA typically involves fever, cough, hemoptysis, and pleuritic chest pain. Angioinvasive IPA is seen predominantly in the setting of neutropenia and the course in neutropenic patients can be rapid, with clinical deterioration over hours to days. Patients with disseminated disease may have additional symptoms related to other sites of infection. *Aspergillus* can extend directly to surrounding areas, including the chest wall (see Fig. 90-27),¹³⁶ mediastinum, and great vessels.¹³⁷

Early diagnosis of IPA is essential for prompt initiation of therapy, which has been associated with improved sur-

vival.¹³⁸ However, multiple factors make the diagnosis difficult, including the lack of symptoms early in the course of illness, challenges in obtaining appropriate tissue for histopathology and culture in critically ill or cytopenic hosts, and the variable sensitivity and specificity of many of the available diagnostic tests. Imaging findings associated with IPA are often nonspecific, including nodules (see eFigs. 90-27, 90-28, and 91-10), consolidation (see eFig. 91-8), cavitation (see eFigs. 90-27 and 90-28), and effusions (see eFig. 91-10). The halo sign, demonstrated by ground-glass opacities surrounding a pulmonary nodule, is the result of alveolar hemorrhage around an infarcted area of the lung (Fig. 38-4A; see eFig. 91-10) and is typically seen early in the course of infection.¹³⁹ The halo sign has a high specificity for IPA in neutropenic patients.¹⁴⁰ The air-crescent sign tends to be seen later in the course of infection (typically with recovery of neutrophils in the neutropenic host) and represents air that has filled the space between necrotic and healthy lung tissue (see Fig. 38-4B).¹⁴¹

Direct microscopy of sputum or BAL lacks both sensitivity (reported ranges from 0% to 90%) and specificity.¹⁴² Histopathologic evaluation of tissue specimens using standard hematoxylin and eosin, periodic acid-Schiff, and/or Gomori's methenamine silver staining with demonstration of characteristic hyphae supports the diagnosis of IPA, but culture or sequence data are required to confirm the identity of the pathogen (see Fig. 38-2). Furthermore, 48% to 70% of tissues with evidence of invasive septate hyphae fail to grow in culture.¹⁴³ When positive, cultures for most *Aspergillus* species typically grow within 48 to 72 hours on standard mycologic media.¹⁴⁴

Noninvasive tests are increasingly used for patients at risk for IPA. These include assays for fungal *galactomannan* (GM) and β -D-glucan. GM is a heteropolysaccharide component of the cell wall of *Aspergillus* and other fungi that is released during hyphal growth. Platelia *Aspergillus* EIA (Bio-Rad Laboratories) is an FDA-approved, commercially available diagnostic for detecting GM in neutropenic and HSCT patients with invasive *Aspergillus*, including IPA. The positive cutoff value is an optical density (OD) index of 0.5. A meta-analysis of 27 studies from 1966 to 2005 using surveillance GM in immunocompromised hosts with invasive

Aspergillus reported an overall sensitivity and specificity of 71% and 89%, respectively.¹⁴⁵ Subgroup analysis showed that test performance was higher in patients with hematologic malignancy (sensitivity, 70%; specificity, 92%) and HSCT recipients (sensitivity, 82%; specificity, 86%) compared to SOT recipients (sensitivity, 22%; specificity, 84%). One potential explanation for the improved performance in patients with hematologic malignancies or HSCT recipients was gained from an in vitro model of the human alveolus showing that detection of GM correlated with its release into the circulation following angioinvasion,¹⁴⁶ which is more common in neutropenic patients.

Assaying BAL specimens for GM by the same enzyme immunoassay may complement assays of serum. A meta-analysis of 30 studies evaluating BAL GM using a cutoff OD index of 0.5 for proven and probable invasive aspergillosis found a sensitivity of 87% and specificity of 89%. Compared to serum GM, BAL GM had a higher sensitivity but a lower specificity. By increasing the positive cutoff value to an OD index of 1, specificity was increased without decreasing sensitivity.¹⁴⁷ This is particularly important in lung transplant patients in whom high rates of colonization with molds such as *Aspergillus* and *Penicillium* can result in false-positive tests for GM. In one study, lung transplant recipients (16 of 81) accounted for more than 40% of false-positive BAL test results for GM.¹⁴⁸ Other factors that compromise the utility of the GM assay include cross-reactivity with other fungi (e.g., *Alternaria*, *Fusarium*, *Geotrichum*, *Histoplasma*, *Paecilomyces*, and *Penicillium*) and false-positive results secondary to the presence of GM in antimicrobials, such as piperacillin-tazobactam, in nutritional supplements, and in Plasmalyte. However, the magnitude of serum GM was shown to have prognostic utility in a single-center study of invasive aspergillosis in allogeneic HSCT recipients, with higher values correlated with higher all-cause mortality.¹⁴⁹ Use of the GM assay to monitor response to treatment and to detect relapse is under investigation.

β -D-glucan, another fungal cell wall component, is used in the diagnosis of invasive aspergillosis as well as other IFIs, including *Candida* and *Pneumocystis*. The FDA approved and commercially licensed assay in the United States is the Fungitell assay, which has a positive cutoff value of 80 pg/mL or greater (sensitivity, 64%; specificity, 92%) for patients with proven or probable invasive aspergillosis.¹⁵⁰ β -D-glucan may be detectable earlier in the course of invasive aspergillosis than is GM.¹⁵¹ False-positive β -D-glucan results may be associated with hemodialysis using cellulose membranes, intravenous immunoglobulin, and bacterial bloodstream infections.¹⁴² In a study to assess the utility of serially monitoring lung transplant recipients with the β -D-glucan assay, 90% of subjects without an IFI had at least one positive β -D-glucan result (≥ 80 pg/mL), leading to a low positive predictive value (9%).¹⁵² Similar issues were encountered in a study using β -D-glucan to monitor for invasive candidiasis in an intensive care unit; 45% of subjects had false-positive results, which were ultimately attributed to receipt of intravenous immunoglobulin and hemodialysis.⁶³

Nucleic acid-based tests including PCR have been explored in the diagnosis of invasive aspergillosis, although none of these have been incorporated into formal diagnostic criteria. A meta-analysis of PCR testing of blood, plasma,

or serum reported a sensitivity and specificity of 75% and 87%, respectively.¹⁵³ Avni and associates¹⁵⁴ found comparable performance of BAL-PCR versus BAL GM testing (using an OD index of 0.5) as well as improved sensitivity with stable specificity when used together, suggesting a possible advantage to combination testing. To date there is no FDA-approved nucleic acid assay for *Aspergillus* in the United States. Attempts at standardization¹⁵⁵ and the availability of a commercial PCR platform¹⁵⁶ are necessary steps toward validation and routine clinical use. Newer diagnostics, including a lateral flow device incorporating a monoclonal antibody, JF5, to detect an *Aspergillus* extracellular glycoprotein antigen may provide rapid and inexpensive point-of-care testing.¹⁵⁷

Diagnostic criteria for IPA have been proposed by the Mycoses Study Group/European Organization for Research and Treatment of Cancer and include proven, probable, and possible invasive aspergillosis.¹⁵⁸ A diagnosis of *proven* IFI requires microscopic evidence of *Aspergillus* tissue invasion or a positive culture from a normally sterile site. A diagnosis of *probable* IPA requires an at-risk host, corroborating radiographic findings, and direct (e.g., culture) or indirect mycologic evidence (e.g., positive serum, plasma, or BAL GM, or positive serum β -D-glucan). Other clinical algorithms continue to be introduced to assist in differentiating *Aspergillus* colonization from true invasive aspergillosis in critically ill intensive care unit patients without clear predisposing host factors but with positive respiratory specimens and/or clinical concern for invasive aspergillosis.¹⁵⁹

Treatment. As with other IFIs, management of IPA may involve a combination of surgical, pharmacologic, and other adjunctive interventions. Attempts to restore host immunity should be made wherever feasible, being mindful of the risk for IRIS.¹⁶⁰ Indications for surgical intervention include life-threatening hemoptysis, lesions contiguous to the great vessels and/or pericardium, and invasion of the chest wall, as well as isolated lesions in patients about to undergo intensive chemotherapy or HSCT.⁸⁵ The drug of choice for IPA is voriconazole, based on recommendations from both the IDSA⁸⁵ and American Thoracic Society⁴² and data from a large prospective randomized trial of invasive aspergillosis that demonstrated significantly better response and overall survival in those treated with voriconazole than those treated with AmB-d.¹⁶¹ The dose of voriconazole for IPA is 6 mg/kg intravenously every 12 hours on day 1, followed by 4 mg/kg every 12 hours thereafter. Therapy can be transitioned to the oral route once the patient is stable and tolerating oral medications. While most patients are treated for a minimum of 6 to 12 weeks, the total duration of pharmacologic therapy for IPA is not clearly defined and is dependent upon the immune status of the host and clinical response to treatment (eFig. 38-5).

Posaconazole may be an effective alternative to voriconazole, although it is most often used as salvage therapy because it has not been studied as primary treatment. In patients with invasive aspergillosis refractory or intolerant to other antifungal therapies, response to posaconazole was superior (45/107, 42%) compared with the external control group (22/86, 26%), primarily treated with AmB or itraconazole.¹⁶² Other researchers have also shown success with posaconazole as salvage therapy.¹⁶³

Azole resistance in *Aspergillus* was first reported with *A. fumigatus* in 1997 and appears to be increasing in frequency.^{164,165} The known mechanism of resistance is due to sequence variation in the fungal *cyp51A* gene, which encodes the drug target, 14- α -demethylase.¹⁶⁵ Many of these sequence variants result in cross-resistance between the azole compounds, namely itraconazole, voriconazole, and posaconazole. Although interpretive breakpoints defining clinical resistance have yet to be established for molds, standard methods for testing filamentous fungi have been validated,¹⁶⁶ and epidemiologic cutoff values (which define susceptibility using the MIC distribution of wild-type *Aspergillus* strains lacking known azole resistance mechanisms) have been proposed.¹⁶⁷ While epidemiologic cutoff values do not predict outcomes, they may aid in detecting isolates with potential resistance mutations, including those in *cyp51A*. Some experts advocate MIC testing as a screen for the presence of resistance mutations in patients with invasive aspergillosis that fail to respond to azole therapy.

Polyenes are used for the treatment of IPA in the setting where mucormycosis remains in the differential diagnosis or in patients intolerant or refractory to azoles. The lipid formulations of AmB are currently preferred because of their reduced nephrotoxicity compared with that of AmB-d. Currently, the IDSA recommends ABLC 5 mg/kg/day or LAmB 3 to 5 mg/kg/day for the treatment of IPA. LAmB 3 mg/kg/day was compared with LAmB 10 mg/kg/day in a double-blind trial of patients with proven or probable invasive aspergillosis to assess whether higher doses would improve response; there was no clinical advantage with the higher dose but there was significantly more hypokalemia and nephrotoxicity.¹⁶⁸

Echinocandins may be used in patients who are refractory or intolerant to other therapies, although randomized controlled trials evaluating echinocandins as primary therapy for invasive aspergillosis have not been performed. In one study, 83 adults with probable/proven invasive aspergillosis, including 64 with IPA were treated with caspofungin; 45% (50% of those with IPA) obtained a complete or partial response.^{169,170} Based on these data, caspofungin was cleared by the FDA as salvage therapy for invasive aspergillosis. For micafungin, a large report from Japan indicated a 71% (90 of 130) clinical response rate in patients with invasive aspergillosis treated with micafungin monotherapy (doses ranged from 50 to 300 mg/day) as first-line therapy.¹⁷¹

Given the high mortality associated with IPA, combination therapy is often considered. While in vitro and in vivo^{172,173} data support a role for combination therapy, the IDSA does not recommend using combination therapy as first-line therapy for invasive aspergillosis, due to the lack of data from a randomized controlled trial. When combination therapy is used, echinocandins are most often paired with polyenes or azoles based on their activity at a different site (fungal cell wall) compared with the azoles and polyenes (fungal membrane).^{174,175} A randomized controlled trial comparing voriconazole monotherapy with voriconazole plus anidulafungin in patients with invasive aspergillosis is underway.¹⁷⁶ Other adjunctive measures used to optimize outcomes of IPA include granulocyte or granulocyte-macrophage colony stimulating factor, interferon-gamma, and granulocyte infusions.⁸⁵

Tracheobronchial Aspergillosis

Epidemiology and Pathogenesis. *Tracheobronchial aspergillosis* (TBA) should be considered as a spectrum, including mild tracheobronchitis and obstructive, ulcerative, and pseudomembranous TBA, often with more than one form present concurrently.¹⁷⁷ Mild tracheobronchitis demonstrates only superficial mucosal inflammation; obstructive, ulcerative, and pseudomembranous forms may be superficial or progress to involve the entire bronchial wall with necrotizing tracheobronchitis and invasion of the surrounding tissue.¹⁷⁸ A rare form of IPA, TBA is most commonly encountered in lung and heart-lung transplant recipients,^{179,180} although it has been reported in patients with advanced HIV¹⁸¹ and hematologic malignancies, including patients undergoing HSCT.^{182,183}

Clinical Manifestations, Diagnosis and Treatment. In lung and heart-lung transplant recipients, TBA is often discovered early in the posttransplant period when patients may have ulceration and/or pseudomembrane formation at the bronchial anastomotic site visible by bronchoscopy (Fig. 38-5), even without symptoms.¹⁸⁴ In contrast, patients with hematologic malignancies are typically symptomatic at the time of discovery of TBA with productive cough, dyspnea, fever, wheezing, stridor, hemoptysis, and respiratory failure.^{177,185} Early diagnosis is crucial given the potential for progressive symptoms and disseminated infection and complications including bronchial obstruction, anastomotic rupture, and bronchopleural or bronchoarterial fistulas.^{179,186} While chest imaging may demonstrate bronchial wall thickening, luminal narrowing, and/or endobronchial lesions (eFig. 38-6),^{185,187} it cannot make the diagnosis. Serum GM is of limited value for tracheobronchial aspergillosis.¹⁸⁸ Diagnosis is made via bronchoscopy with visualization of plaques, ulceration, pseudomembranes, and obstructive mucous plugs and/or masses (Fig. 38-6) together with pathologic and microbiologic findings.

Figure 38-5 Tracheobronchial aspergillosis. Bronchoscopic visualization of the right mainstem bronchus in a lung transplant recipient demonstrates tracheobronchial aspergillosis with *Aspergillus fumigatus*. Stenosis and extensive necrotic pseudomembranes and debris are seen at the anastomotic site. (Courtesy Dr. Scott Shofer, Duke University Medical Center, NC.)

Subglottic mass in a patient with a hematologic malignancy and prolonged neutropenia with histopathologic and culture data consistent with *Aspergillus fumigatus* tracheobronchial aspergillosis. **A**, Bronchoscopic visualization beyond the vocal cords revealing a friable subglottic tracheal mass with surrounding mucosal edema resulting in approximately 50% obstruction. **B**, Movement of the mass with breathing creating a ball-valve, extrathoracic obstruction. **A**, closing partially with inspiration, **B** opening partially with expiration. (Courtesy Kamran Mahmood, MD, MPH, Duke University Medical Center.)

Treatment of TBA is similar to that for other forms of IPA.⁸⁵ Voriconazole is the preferred first-line therapy; other antifungals including itraconazole, posaconazole, AmB, and echinocandins may be used. Systemic therapy has also been combined with aerosolized and topical endobronchial application of AmB-d (the latter in doses ranging from 2 to 50 mg) in severe TBA in lung transplant recipients.¹⁸⁹

Chronic Pulmonary Aspergillosis

Epidemiology and Definitions. Chronic pulmonary aspergillosis includes three entities, according to a recent nomenclature based on radiographic and clinical findings.¹⁹⁰ The first entity, termed *chronic cavitary pulmonary aspergillosis*, represents chronic cavitary disease that may be accompanied by new cavity formation, but does not demonstrate hyphal invasion into the surrounding parenchyma. The second entity, *subacute IPA*, is more invasive. In contrast to IPA, subacute IPA is characterized by slower progression and typically arises within a thin walled cavity. In contrast to aspergilloma, subacute IPA includes destruction of the pulmonary parenchyma and hyphal invasion into surrounding tissue, including the chest wall and vertebrae. The third entity, *chronic fibrosing pulmonary aspergillosis*, is defined by marked fibrosis around the cavity. These chronic forms of aspergillosis are found in individuals with structural lung disease including prior mycobacterial disease, sarcoidosis, lung cancer, emphysema, and asthma.¹⁰⁶ However, subacute IPA is also seen in patients with variable degrees of immunosuppression or comorbidities including diabetes, alcoholism, and advanced HIV.^{191,192} Progression from chronic cavitary pulmonary aspergillosis to subacute IPA during therapy with steroids demonstrates the overlap of these entities.¹⁹⁰ Sequence polymorphisms in the genes encoding mannose-binding lectin and surfactant are associated with chronic forms of pulmonary aspergillosis in some patients.^{97,193}

Clinical Presentation, Diagnosis, and Treatment. Patients with subacute IPA typically exhibit systemic symp-

toms. The course is usually indolent, with cough, dyspnea, hemoptysis, fatigue, and weight loss.¹⁹⁰ Imaging findings include cavities of variable wall thickness (eFig. 38-7), consolidation, and paracavitary opacities.^{105,190} Precipitating antibodies to *Aspergillus* are detectable in serum of nearly all patients. Respiratory cultures may be positive for *Aspergillus*, and other diagnostics such as a positive serum and/or BAL GM as well as elevated erythrocyte sedimentation rate or C-reactive protein may further support the diagnosis. Histopathologic findings of resected lesions demonstrate inflammation with hyphae both within the cavity and invading the surrounding tissue, with or without granulomas.

Treatment of all forms of chronic pulmonary aspergillosis is with systemic antifungal therapies such as voriconazole.⁸⁵ Given the long-term therapy required, oral treatment is preferred. However, in patients with severe disease, initial treatment with intravenous voriconazole or AmB may be warranted.⁴²

MUCORMYCOSIS

EPIDEMIOLOGY

Mucormycosis is caused by molds in the order Mucorales in the subphylum Mucormycotina.¹⁹⁴ *Rhizopus* and *Mucor* are the genera most commonly associated with infections although *Apophysomyces*, *Cunninghamella*, *Rhizomucor*, *Syncephalastrum*, and others also cause disease.¹⁹⁵⁻¹⁹⁸ These are ubiquitous molds found in soil and decaying plant material which gain access to the host via inhalation, skin penetration or, less commonly, ingestion. Infection sites include skin and soft tissue, rhino-orbital-cerebral, gastrointestinal, and lower respiratory tract, as well as disseminated infection with multiorgan involvement.^{197,199,200} In a retrospective series of 929 cases of mucormycosis, the most commonly affected patients were those with poorly controlled diabetes, among whom sinus involvement, including

rhino-orbital-cerebral infections, was the most frequent presentation. Patients with hematologic malignancies or undergoing HSCT were the second most commonly affected group in whom pulmonary infections predominated.¹⁹⁹ Mucormycosis is the third most common IFI in the HSCT population, representing 8% of IFIs,²⁴ compared with 2% of IFIs in SOT recipients.²³ Surveillance data suggest an increasing incidence of mucormycosis,^{24,201} and multiple reports of “breakthrough” mucormycosis in patients receiving voriconazole²⁰²⁻²⁰⁶ raise the question of whether voriconazole exposure is a risk. However, this association is likely multifactorial, including changes in immunosuppression and patient survival, and not solely attributable to the drug.

PATHOGENESIS

After the fungal spores gain access to the host, mononuclear and polymorphonuclear phagocytes normally serve as a primary host defense against invasion.²⁰⁷ However, hyperglycemia and acidosis in people with poorly controlled diabetes impair phagocyte function.²⁰⁸ Moreover, growth of pathogenic Mucorales is enhanced by free iron; thus iron overload and treatment with deferoxamine, which behaves as a siderophore that increases iron availability to the fungus, are associated with mucormycosis. Likewise, systemic acidosis increases free iron by decreasing iron binding to transferrin.²⁰⁰ Similar to *Aspergillus* and certain other pathogenic molds, mucormycosis is angioinvasive, resulting in thrombosis, infarction, and tissue necrosis, with risk for dissemination to other sites. Strong experimental evidence indicates that one mechanism that promotes angioinvasion by *Rhizopus oryzae* (the most common species in patients with mucormycosis) is glucose- and iron-induced expression of glucose-regulated protein 78 by vascular endothelial cells, which promotes binding of *Rhizopus* to endothelial cells in vitro and in vivo.²⁰⁹ The *Rhizopus* ligands for endothelial cell glucose-regulated protein 78 are two closely related surface proteins, CoH2 and CoH3, which mediate invasion of endothelial cells in vitro and are essential for virulence in vivo.²¹⁰

CLINICAL MANIFESTATIONS

Pulmonary mucormycosis is often acute and severe, particularly in neutropenic patients, with fever, cough, dyspnea, pleuritic chest pain, and hemoptysis.^{211,212} In patients with diabetes, the course may be more subacute.²¹³ Pulmonary involvement may also be associated with life-threatening hemoptysis due to vascular invasion by the fungus and the infection may disseminate or expand locally to involve contiguous structures, including the mediastinum and chest wall.²¹¹ Although uncommon, broncho-pleural, bronchocutaneous, and bronchoarterial fistulas have been reported.^{211,214} Tracheobronchial infection has been reported in patients with diabetes and in lung transplant recipients.²¹⁵ Endoscopic findings include luminal narrowing or obstruction with pseudomembranes and necrosis.

Imaging findings are similar to those described with IPA and include nodular (eFig. 38-8) and mass (eFigs. 38-9 and 38-10) lesions, ground-glass opacities, and consolidative

Figure 38-7 Mucormycosis. Axial chest CT displayed in lung windows performed in a hematopoietic stem cell transplant patient demonstrates left upper lobe consolidation (arrowheads) with surrounding ground-glass opacity consistent with the “reversed halo” sign.

and cavitory (see eFig. 91-9) lesions. The presence of multiple 10 or more pulmonary nodules and pleural effusions favors the diagnosis of invasive pulmonary mucormycosis over IPA, although this is not absolute.²¹² Both the halo sign and the reversed halo sign (ground-glass opacity surrounded by a ring or crescent of consolidation; Fig. 38-7) may be seen,¹⁴⁰ but in at least one series, the reversed halo was more common in mucormycosis.²¹⁶

DIAGNOSIS

The diagnosis is typically made based on a combination of clinical, imaging, culture, and histopathologic findings. Currently available noninvasive tests, such as assays of serum β -D-glucan, do not contribute to the diagnosis, because the molds that cause mucormycosis do not produce β -D-glucan. Direct examination of sputum and BAL specimens may show the characteristic broad 10- to 20- μ m, ribbon-like, irregularly branching hyphae.²¹⁷ Potassium hydroxide wet mounts enhanced with calcofluor (which stains chitin) may assist in detecting the fungus in fresh specimens; periodic acid-Schiff and/or Gomori’s methenamine silver staining are used to visualize the fungi in tissue samples.²¹⁸ Prior receipt of mold-active therapy may alter the characteristic morphology in fresh specimens. Although

organisms may be visualized in tissue or respiratory specimens, cultures may be negative in up to one third of cases.²¹⁹ The use of diagnostic techniques including direct PCR of tissue samples is under investigation.^{218,220} Because of the difficulties in obtaining diagnostic specimens in many of these critically ill hosts, noninvasive diagnostics, including quantitative PCR of serum, are also under investigation.²²¹

TREATMENT

Early treatment for mucormycosis is essential for optimal outcomes²²² and includes pharmacologic, medical (reducing immunosuppression, correcting metabolic acidosis, and optimizing control of diabetes), and often surgical intervention (eFigs. 38-11 and 38-12). Surgery, when feasible, is useful for debulking infection and preventing spread to contiguous structures, and is associated with decreased mortality compared to medical treatment alone.^{223,224}

Controlled trials to guide antifungal selection for mucormycosis are lacking, so recommendations are based on information gained through in vitro testing, animal models, and clinical observations. Polyenes remain the agents of choice in the management of mucormycosis. AmB-d has largely been replaced by lipid formulations. LAmB is considered by many to be the preferred agent, due to reduced nephrotoxicity, superior activity in murine models of infection,²²⁵ retrospective clinical data,²²⁶ and rabbit models showing improved CNS penetration compared to both AMB-d and ABLC.²²⁷ LAmB is typically initiated at a dosage of 5 mg/kg/day but has been increased to 10 to 15 mg/kg/day in severe infections that fail to respond.²²⁸ Among the azoles active against molds, itraconazole and posaconazole have in vitro activity against mucormycosis; there is more clinical experience with posaconazole, especially in cases refractory to or intolerant of polyenes or for step-down therapy following induction with a polyene. Among 91 cases of mucormycosis in which posaconazole was used for salvage therapy (either alone or in combination), 60% showed complete or partial response at 12 weeks.²²⁹ Similar responses were reported in a retrospective review of 96 cases of mucormycosis.²³⁰ The treatment dosage of posaconazole suspension is 200 mg 4 times a day and is typically administered until there are clinical and radiographic evidence of resolution, accompanied by restoration of immune functions. Therapeutic drug monitoring with the suspension formulation to ensure adequate levels of posaconazole is especially important in management of mucormycosis given concerns for reduced bioavailability.²³¹ However, posaconazole extended release tablets were approved by the FDA in late 2013 and available data suggests improved overall bioavailability compared with posaconazole suspension^{231a,231b,302} and in 2014 the FDA approved an intravenous formulation.³⁰² Furthermore, the activity of posaconazole against the agents of mucormycosis is variable depending on the genus and species.²³²⁻²³⁴ Thus identification of the infecting pathogen is critical when choosing posaconazole as a therapeutic option.

Echinocandins do not have significant in vitro activity against agents of mucormycosis and should not be used as monotherapy in the treatment of these infections. However, there may be a role for polyene-echinocandin combination

therapy. The gene encoding β -D-glucan synthase, the target enzyme of the echinocandins, has been identified in *Rhizopus oryzae*. Furthermore, studies have shown improved survival with caspofungin compared with no treatment in mice²³⁵ and with polyene-echinocandin combination therapy.^{236,237} Clinical data for combination therapy are limited and mixed. A small retrospective study from 2 centers evaluated 41 patients, most of whom had diabetes (83%) with rhino-orbital and rhino-orbital-cerebral mucormycosis, and found polyene-echinocandin combination therapy improved outcomes compared to polyene monotherapy.²³⁸

The use of adjunctive therapy with the iron chelator deferasirox showed promise in both murine models and a small clinical trial.^{239,240} However, a multicenter clinical trial comparing LAmB/deferasirox to LAmB/placebo found a significantly higher 90-day mortality in those receiving deferasirox.²⁴¹ The increased mortality may have been related to imbalanced enrollment, because more patients in the deferasirox treatment group had hematologic malignancies and neutropenia, which are associated with poorer outcomes. The role of deferasirox in the management of mucormycosis remains unclear, but its use is not currently recommended. Other adjunctive agents that have been used include hyperbaric oxygen, granulocyte colony stimulating factors and interferon gamma.²⁴²

NON-ASPERGILLUS HYALINE HYPHOMYCETES

EPIDEMIOLOGY AND PATHOGENESIS

Hyalohyphomycosis refers to infections caused by septate molds with colorless or lightly pigmented hyphae. *Aspergillus* is the most common of the hyaline molds; however, non-*Aspergillus* hyphomycetes, including *Acremonium*,^{243,244} *Fusarium*,²⁴⁵ *Geosmithia*,^{246,247} *Paecilomyces*,²⁴⁸ *Scedosporium*,²⁴⁹ and *Trichoderma*,²⁵⁰ among others, are increasingly reported.^{80,201,251} These pathogens can cause infection in immunocompetent or immunocompromised hosts. *Fusarium* and *Scedosporium* are the most common causes of infection from this group in SOT and HSCT recipients.²⁰¹

More than 50 species of *Fusarium* have been identified; some are common pathogens of plants, including vegetables. *F. solani* is the species most often associated with human infection, although *F. oxysporum* and *F. moniliforme* have also been reported.^{201,245} *Scedosporium apiospermum* (the asexual form of *Pseudallescheria boydii*) and *S. prolificans* are the most common pathogenic *Scedosporium* species.²⁵² Clinically relevant species of *Acremonium* are difficult to identify based on morphology alone and may be misidentified as other molds such as *Fusarium*.²⁴⁴ The species associated with clinical disease include *A. falciforme*, *A. kiliense*, *A. roseogriseum*, and *A. strictum*.²⁴³ *Paecilomyces* is another emerging pathogen that historically was represented by infections with *P. variotii* and *P. lilacinus*. More recently, *P. variotii* has been divided into multiple species,^{253,254} and *P. lilacinus* has been reclassified as *Purpureocillium lilacinum*.²⁵⁵ *Geosmithia argillacea*, often misidentified as *P. variotii*,^{247,254} has also been associated with severe pulmonary

infections, particularly in patients with CF²⁴⁶ and chronic granulomatous disease.²⁴⁷ Finally, infections with *Trichoderma*, particularly *T. longibrachiatum*, are increasingly reported.²⁵⁰

Because the majority of these molds are ubiquitous in nature, they are often considered environmental saprophytes when recovered from clinical specimens. Infections are commonly associated with traumatic or nontraumatic inoculation with localized nail, eye, skin, and soft tissue infections. Inhalation of airborne conidia (spores) can lead to sinopulmonary infections ranging from mild allergic sinusitis and ABPM to severe and invasive sinopulmonary infections. Many of these pathogens are uniquely capable of adventitious sporulation, the ability to sporulate in infected tissue, which when coupled with endovascular invasion, results in fungemia. Although fungemia is uncommon in *Aspergillus* infections, it is reported in more than 50% of patients with disseminated *Fusarium* infections.²⁵⁶ Adventitious sporulation has also been described with *Acremonium* and *Paecilomyces*,²⁵⁷ *Scedosporium*,²⁵⁸ and *Trichoderma*.²⁵⁰ Mycotoxin production and adherence factors that promote colonization and infection may contribute to the pathogenicity of these molds.²⁵⁹

Localized skin, soft tissue, ocular, and sinopulmonary infections are seen in immunocompetent hosts, and chronic colonization can be present in patients with lung disease (e.g., bronchiectasis, pulmonary fibrosis). Fungemia and invasive infections develop predominantly in patients with impaired cellular and/or humoral immunity. In these patients, dissemination of infection from the lungs or local spread from the sinuses can result in CNS extension and brain abscess formation. Invasive infection is limited to immunodeficient patients with one notable exception: In immunocompetent near-drowning victims, severe CNS and sinopulmonary infections with *S. apiospermum* have been described, presumably because the forceful submersion in water resulted in alveolar damage with fungal penetration and severe fungal pneumonia.^{260,261}

CLINICAL PRESENTATION AND DIAGNOSIS

The respiratory presentation of non-*Aspergillus* hyalohyphomycosis resembles that of invasive aspergillosis and includes sinusitis, ABPM, tracheobronchial disease, pneumonia, and pleuropulmonary infections. Patients may present with fever, sinus congestion and pain, cough, purulent sputum, and hemoptysis (eFig. 38-13). In patients with disseminated infection, skin manifestations may be an early clue. Skin lesions are typically painful, erythematous, nodular eruptions that rapidly develop central pallor and necrosis (Fig. 38-8).

The diagnosis of infection with one of these pathogens is challenging, due to difficulties in differentiating between fungal colonization and true infection and in obtaining appropriate tissue specimens for evaluation. Furthermore, while histopathologic, cytopathologic, or direct microscopic examination from affected tissue is critical in making the diagnosis,¹⁵⁸ these findings do not discriminate amongst the hyaline molds; culture data are required for definitive identification and diagnosis. Radiographic findings (e.g., pulmonary nodules, cavitation, and halo, reversed halo, and air-crescent signs) provide further support for infection but

Figure 38-8 Disseminated *Fusarium*. Skin lesions in a patient with disseminated *Fusarium* infection demonstrating central necrosis with surrounding erythema.

are not specific. Noninvasive diagnostic testing such as serum or BAL GM, used primarily for the diagnosis of invasive aspergillosis, may cross-react with the non-*Aspergillus* hyaline molds including *Fusarium*,²⁶² *Paecilomyces*, and *Penicillium*,²⁶³ but lack both sensitivity and specificity in diagnosing these infections. The role of other molecular diagnostics such as nucleic acid assays or matrix-assisted laser desorption/ionization time of flight mass spectrometry continues to be defined.

TREATMENT

Treatment of these infections is multimodal. Immunosuppression should be reduced whenever feasible, and augmentation of host responses with growth factors and granulocyte transfusions should be considered. Removal of foreign devices and surgical intervention/débridement, particularly in localized disease, are also critical in management. Many of these pathogens are intrinsically resistant to conventional antifungal therapies and/or have species-dependent variability in MICs to antifungal drugs; identification to the species level is imperative. In some cases (e.g., *Fusarium* for which AmB activity is variable), susceptibility testing may provide additional guidance in drug selection.

Exemplifying the complexity of managing infections with non-*Aspergillus* mold infections, *Fusarium* and *Scedosporium* species exhibit variable levels of resistance to most antifungals.²⁶⁴ *F. solani*, the most common of the clinical isolates, is also the most resistant, with high MICs to voriconazole and posaconazole.^{245,256} ABLC treatment of invasive *Fusarium* infections in patients with hematologic malignancy or undergoing HSCT, resulted in improvement or cure of infection in 46% of patients evaluated.²⁶⁵ Pooled analysis of 21 patients with invasive *Fusarium* infections treated with voriconazole showed similar success in 43%, resulting in FDA approval of voriconazole for refractory infections or intolerance to other therapies.²⁶⁶ While it is not FDA approved for this indication, posaconazole has been used as salvage therapy in patients with hematologic malignancies and invasive Fusariosis.²⁶⁷ *Fusarium* species are intrinsically resistant to echinocandins; however, in combination

therapy with AmB,²⁶⁸ synergy has been demonstrated in vitro and in vivo.^{269,270} Other combinations including lipid formulations of AmB and voriconazole²⁷¹ have been used with clinical success, as have combinations that include terbinafine.²⁷²

Among *Scedosporium* species, *S. prolificans* often demonstrates high-level resistance to all antifungals and has been associated with poor clinical outcomes.²⁵² In contrast, *S. apiospermum* tends to be more susceptible to antifungals, particularly extended-spectrum azoles such as voriconazole.²⁷³ Successful responses to voriconazole were demonstrated in 63% (15 of 24) of patients with *S. apiospermum* infections resulting in FDA approval for this specific *Scedosporium* species. A more recent compilation of the data discussed herein plus additional cases of invasive *Scedosporiosis* obtained via the voriconazole global clinical trials database (Pfizer) reported a successful therapeutic response in 57% (61 of 107) of patients with notably higher success in *S. apiospermum* (45 of 70, 64%) compared with *S. prolificans* (16 of 36, 44%) infections.²⁷³ Combination therapies of voriconazole with terbinafine²⁷⁴ or with an echinocandin with or without AmB,²⁷⁵ particularly in multidrug-resistant infections, may be effective. AmB has poor activity against *P. lilacinum* but is highly active against *P. variotti*.²⁷⁶ In addition, while voriconazole demonstrates low MICs with *P. lilacinum*, MIC ranges are notably higher for the *P. variotti* species complex such that posaconazole is the preferred extended azole for this group.^{254,277}

DEMATIACEOUS (MELANIZED) FUNGI

The dematiaceous fungi represent an assorted group of molds with more than 50 genera and 100 species.²⁷⁸ While their presence in culture is often dismissed as contamination, they are increasingly associated with infection and can be seen in immunodeficient and immunocompetent hosts. Dematiaceous fungi contain melanin in their cell walls, which contributes to their pathogenicity and accounts for the dark brown color seen in culture and/or histopathology.²⁷⁹ These fungi are found in soil and vegetation worldwide and can gain entry into the host via inhalation or the cutaneous route. They are responsible for phaeohyphomycoses, an array of infections including skin and soft tissue infections, allergic and invasive sinus disease, or pneumonia, and ocular, CNS, and disseminated infections. Isolated skin and soft tissue infections are more common in immunocompetent hosts, whereas pulmonary and disseminated infections are predominantly seen in immunosuppressed patients. *Alternaria*, *Bipolaris*, *Cladophialophora*, *Curvularia*, *Exophiala*, *Exserohilum*, *Ochroconis* (previously *Dactylaria*), and *Phialophora* are some of the more common black molds associated with infection. Intrathecal injection of *Exserohilum*-contaminated corticosteroids recently led to a large outbreak of fungal meningitis in immunocompetent patients in the United States.^{280,281} *Bipolaris* and *Curvularia* are often associated with allergic and chronic inflammatory diseases including allergic fungal sinusitis and ABPM.²⁸² *Cladophialophora bantiana*,^{283,284} *Rhinocladiella*

mackenziei,^{285,286} *Exophiala* (*Wangiella*) *dermatitidis*²⁸⁷ and *Ochroconis gallopava*²⁸⁸ have a predilection for dissemination to the brain and can cause severe disease in immunocompetent and immunosuppressed patients.²⁸⁹ Disseminated infections with dematiaceous molds have been associated with mortality rates of up to 80%.²⁹⁰

Sinopulmonary manifestations with the dematiaceous molds include asymptomatic nodules, ABPM, and allergic fungal sinusitis, as well as invasive sinus and pulmonary infections. The latter two entities more commonly infect immunocompromised hosts and those with preexisting lung disease. CT findings are often nonspecific (eFig. 38-14) and consistent with that described with the other invasive pulmonary mycoses. Fungal elements seen on direct microscopy from clinical specimens can be associated with either colonization or contamination; documentation of tissue invasion is essential for diagnosis. Pigmented hyphae can be seen on standard hematoxylin and eosin stains. However, the Fontana Masson stain is often preferred to ensure that those with decreased amounts of pigmentation are not misidentified as hyaline molds.²⁹¹

As with other invasive molds, treatment includes reduction of immunosuppression and surgical debulking (when feasible) to augment antifungal therapies. Susceptibility breakpoints for antifungals have not been defined for the dematiaceous molds. Although resistance to AmB has been seen, AmB demonstrates good in vitro activity against most of the dematiaceous molds. However, the newer extended-spectrum azoles have the best in vitro activity against the majority of dematiaceous molds^{292,293} and are used more frequently given their improved toxicity profile. Combination therapies including azoles, terbinafine, and echinocandins have been employed for severe disease; however, an optimal regimen has not been defined.²⁹¹

Key Points

- Invasive pulmonary aspergillosis may have a clinical presentation similar to that of other angioinvasive molds such as mucormycosis and the non-*Aspergillus* hyphomycetes such as *Fusarium* and *Scedosporium*.
- β -D-glucan is a component of the cell wall of some but not all fungi and can be a useful noninvasive diagnostic aid in serum or bronchoalveolar lavage.
- Voriconazole is the treatment of choice for invasive pulmonary aspergillosis. The total duration of therapy depends on the immune status of the host and clinical and radiographic response to infection. However, patients are treated for a minimum of 6 to 12 weeks.
- Although mucormycosis can be associated with a multitude of clinical manifestations with multiorgan involvement, the most common presentations include rhino-orbital-cerebral and pulmonary infections, particularly in those with poorly controlled diabetes and in immunodeficient patients, especially those with hematologic malignancies.
- *Candida* pneumonia is rare and develops most often following candidemia and dissemination to the lung in immunocompromised populations.
- Combination antifungal therapy may offer benefit in infections due to drug-resistant fungi.

eFigure 38-5 Invasive *Aspergillus* infection: treatment response. A, Axial chest CT performed for a severely immunosuppressed patient following stem cell transplantation shows a right lower lobe cavity (arrow) and poorly defined nodule (arrowhead), consistent with invasive pulmonary aspergillosis. B, Axial chest CT performed following 6 weeks of antifungal therapy shows involution of the right lower lobe cavity (arrow) with reduction in size of the right lower lobe nodule (arrowhead). (Modified from Gotway MB, Dawn SK, Caoili EM, et al: The radiologic spectrum of pulmonary *Aspergillus* infections. *J Comput Assist Tomogr* 26:159–173, 2002.)

eFigure 38-6 *Aspergillus tracheitis*. Axial chest CT performed in a 62-year-old woman immunosuppressed following heart-lung transplantation shows high attenuation plaques (*arrowheads*) within the trachea, confirmed on bronchoscopy to represent *Aspergillus* infection. (Modified from Gotway MB, Dawn SK, Caoili EM, et al: The radiologic spectrum of pulmonary *Aspergillus* infections. *J Comput Assist Tomogr* 26:159–173, 2002.)

eFigure 38-7 Subacute invasive pulmonary aspergillosis (chronic necrotizing aspergillosis): slowly progressive cavitation. **A**, Axial chest CT in a patient with AIDS and diabetes mellitus shows a small cavity with an eccentrically thickened wall and early internal opacity (*arrowhead*). **B**, Focused frontal chest radiograph (**B**) and axial chest CT (**C**) performed 9 months after **A** shows increased size of the cavity with increasing wall thickness and irregularity as well as progression of the intracavitary opacity. Focused frontal chest radiograph (**D**) and axial chest CT (**E**) performed 15 months after **A** now shows an eccentrically thickened left upper lobe cavity with an internal fungus ball. (Modified from Gotway MB, Dawn SK, Caoili EM, et al: The radiologic spectrum of pulmonary *Aspergillus* infections. *J Comput Assist Tomogr* 26:159–173, 2002.)

eFigure 38-8 Mucormycosis: multiple nodules. A–E, Axial chest CT displayed in lung windows performed in a severely immunosuppressed patient shows multiple, bilateral nodules (*arrowheads*), some associated with bronchi (right lower lobe in **D**, and left upper lobe in **B**), and some with ground-glass opacity halos (left upper lobe in **C**). (Courtesy Michael Gotway, MD.)

eFigure 38-9 Mucormycosis: large nodule/mass. Axial chest CT displayed in lung windows performed in a severely immunosuppressed patient shows an irregular opacity just exceeding 3 cm in size in the subpleural right chest lobe (**A**, **B**), proven to reflect *Mucor* on biopsy. Small satellite nodules (*arrowheads*) are seen along the inferior margin of the lesion in **C**. (Courtesy Michael Gotway, MD.)

eFigure 38-10 Mucormycosis: mass with chest wall invasion. **A**, Frontal chest radiograph performed in a severely immunosuppressed patient shows a masslike subpleural opacity in the left upper lobe. Focused axial chest CT displayed in lung (**B**), soft tissue (**C**), and bone (**D**) windows shows the subpleural mass is necrotic (note low attenuation centrally in **C**) associated with chest wall invasion, evidenced by rib destruction (**D**, *arrowheads*). (Courtesy Michael Gotway, MD.)

eFigure 38-11 Mucormycosis: treatment response. **A** and **B**, Axial chest CT displayed in lung windows performed in a severely immunosuppressed patient shows cavitary left upper lobe nodules with internal opacity (*arrows*), proven to reflect *Mucor*. **C** and **D**, Following antifungal therapy and restoration of immune function, the left upper lobe nodules are no longer cavitary and have decreased in size. Follow-up chest CT (not shown) showed complete resolution of the nodules. (Courtesy Michael Gotway, MD; case by Robert Viggiano, MD, Pulmonary and Critical Care Medicine, Mayo Clinic, Scottsdale, AZ.)

Figure 38-12 Mucormycosis: treatment response. **A**, Axial chest CT displayed in lung windows performed in a severely immunosuppressed patient shows a dominant right lower lobe nodule associated with an air bronchogram (*arrow*) and small subpleural left lower lobe nodule (*arrowhead*) due to *Mucor*. **B**, Follow-up chest CT shows enlargement of the right lower lobe nodule (*arrow*) and new left base nodules (*arrowheads*). **C**, Following antifungal treatment and resolution of immunosuppression, the dominant right lower lobe nodule (*arrow*) has decreased significantly in size. Other smaller nodules (*arrowheads*, **A** and **B**) also resolved. (Courtesy Michael Gotway, MD.)

eFigure 38-13 *Scedosporium apiospermum* infection. A–E, Axial chest CT displayed in lung windows in an 80-year-old man with cough and hemoptysis shows right upper lobe and anterior segment left upper lobe bronchiectasis and bronchovascular thickening (*arrowheads*), associated with small nodules (*arrows*, **E**). Bronchoscopy with bronchoalveolar lavage found old blood and recovered *Scedosporium apiospermum* organisms. (Courtesy Michael Gotway, MD.)

Figure 38-14 *Bipolaris* infection. **A–C**, Axial chest CT displayed in lung windows shows right lower lobe peripheral consolidation and numerous small centrilobular nodules (arrowheads, **A** and **B**). Bronchoscopy recovered *Bipolaris* organisms. **D–F**, Axial chest CT displayed in lung windows 2 months after **A–C** and following antifungal therapy shows improvement in basal consolidation and nodules, but appearance of large airway impaction (arrow, **E**). **G–I**, Axial chest CT displayed in lung windows 6 months after **A–C** shows near complete clearing of the right lower lobe process, with mild residual bronchiolitis (arrows). (Courtesy Michael Gotway, MD; case by Paul J. Conomos, MD, Arizona Pulmonary Specialists, Phoenix, AZ.)

INTRODUCTION

Evaluation of a Patient with Possible
Parasitic Infection of the Lung

HELMINTHS

Nematodes

Trematodes

Cestodes

PROTOZOA

Amebiasis

Malaria

Toxoplasmosis

Other Protozoa

INTRODUCTION

Pathogenic parasites that involve the lungs include multicellular helminths as well as unicellular protozoa. Although parasitic infections have classically been associated with tropical and subtropical regions, some are prevalent worldwide. Moreover, travel and immigration have resulted in globalization of formerly geographically restricted infectious diseases, and some of these affect the lungs.

Certain parasitic infections commonly present with pulmonary manifestations, while for others, pulmonary involvement is an unusual complication. With the exception of *Paragonimus*, the lung fluke, few parasites specifically target the lungs, although many helminths migrate through the lungs en route to the gastrointestinal tract. Some parasites that infect the lungs more commonly infect other sites such as the gastrointestinal tract (*Entamoeba*, *Echinococcus*); while others involve the lungs as part of a generalized systemic infection (*Toxoplasma*, *Plasmodium*) (Table 39-1).

Increasing use of immunosuppressive therapy, organ transplantation, and human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), have led to expansion of populations vulnerable to selected parasitic diseases. Moreover, climate change and ecologic perturbations have affected the transmission and geographic range of human parasites. These factors necessitate greater familiarity of all physicians with infections that were previously seen only by specialists in tropical medicine. Clinical presentations of parasitic infections may be nonspecific and pulmonary specialists must be aware of potential pulmonary presentations.

This chapter reviews the pulmonary complications of parasitic infections that exhibit four major patterns: (1) parasites that primarily involve the lungs; (2) parasites that involve the lungs as a transient event in their life cycles; (3) parasites that involve the lungs less often than they involve other organs such as those of the gastrointestinal tract; (4) those that involve the lungs during widespread, systemic infections.

Some topics in this chapter also are discussed in the chapters on pulmonary complications of HIV (Chapter 90) and on eosinophilic lung diseases (Chapter 68).

EVALUATION OF A PATIENT WITH POSSIBLE PARASITIC INFECTION OF THE LUNG

Because specific parasitic infections differ in their geographic distribution, clinicians must consider the diseases that are prevalent in the areas where a patient has traveled or resided. A detailed travel history with information on food and liquids consumed, swimming or wading, insect bites, and medications taken are especially useful in formulating a differential diagnosis. The interval between the time of travel or emigration and the onset of symptoms may provide clues: enteric protozoa or helminthic infections typically present more than 2 weeks after exposure and some parasites such as *Strongyloides*, *Plasmodium vivax* or *ovale*, and *Entamoeba histolytica* can present years after exposure.

Some parasites have complex life cycles with numerous hosts and many are vector borne, while others are acquired by exposures to contaminated soil or water. Many emerging parasitic infections are zoonoses, in which the disease is spread from nonhuman animals to humans. In developing a differential diagnosis for respiratory complaints that may have a parasitic etiology, knowledge of the geographic distribution of various parasites, of potential vectors, and of potential sources of environmental contamination is essential.

Laboratory tests that may be helpful in initial evaluations include a complete blood count with differential, liver function tests, and a basic metabolic panel; in some contexts, examination of the sputum and/or stool samples is essential. Peripheral eosinophilia suggests a potential parasitic cause of pulmonary disease but most protozoan infections are not associated with eosinophilia, and a lack of eosinophilia does not exclude parasitic infection. Diagnosis of intestinal parasites is most often dependent upon microscopic examinations that require adequate specimens and experienced laboratory personnel. Depending on the parasite suspected, stool antigen tests (*E. histolytica*), microscopic examination of blood smears (malaria and *Babesia*), or collection of respiratory samples including sputum or bronchoalveolar lavage (BAL), or serologic tests (*Strongyloides* enzyme-linked immunosorbent assay [ELISA]) may be warranted.¹ Specialized laboratories are able to perform

Table 39-1 Characteristics of the Most Common Parasites Causing Pulmonary Pathology

Parasite	Distribution	Pulmonary Manifestation	Diagnosis	Treatment
HELMINTHS				
Nematodes				
Ascariasis: <i>Ascaris lumbricoides</i>	Worldwide, but widely in tropics	Loeffler syndrome, usually 9 to 12 days after exposure to eggs Cough Substernal discomfort Crackles and wheezing Transient opacities	Examination of sputum Eosinophilia during larval migration Stool ova and parasites: usually positive after pulmonary symptoms resolved Serology	Albendazole Mebendazole
Dirofilariasis (dog heartworm): <i>Dirofilaria immitis</i> and <i>D. repens</i>	Worldwide (associated with dogs)	Pulmonary nodule	Usually requires biopsy to rule out other causes	None (benign, so no treatment necessary)
Hookworm: <i>Ancylostoma duodenale</i> and <i>A. caninum</i> ; <i>Necator americanus</i> , <i>N. brasiliense</i>	Worldwide especially tropics	Loeffler syndrome Transient opacities	Eosinophilia during larval migration	Albendazole Mebendazole
Strongyloidiasis (also a hookworm, but unique due to autoinfection cycles): <i>Strongyloides stercoralis</i> (and sometimes other <i>Strongyloides</i> species)	Worldwide but particularly in tropic or subtropical regions	Loeffler syndrome Chronic cough Pneumonia or sepsis in hyperinfection	Sputum examination Eosinophilia during larval migration Stool ova and parasites Serology (cannot discriminate acute vs. past)	Ivermectin (may need longer doses for immunocompromised hosts); due to risk of hyperinfection, consider treating all seropositives
Trichinosis (also a hookworm but encysts): <i>Trichinella spiralis</i>	Worldwide zoonosis	Respiratory distress Radiographic appearance variable	Serology	Albendazole
Tropical pulmonary eosinophilia (lymphatic filariasis): <i>Wucheria bancrofti</i> and <i>Brugia malayi</i>	Tropics, particularly South Asia	Tropical eosinophilic pneumonia with interstitial opacities Chronic cough	Serology, Bronchoalveolar lavage Eosinophilia	DEC Doxycycline (treats symbiont)
Visceral larval migrans (nonhuman ascarid): <i>Toxocara canis</i> and <i>T. cati</i>	Worldwide	Interstitial opacities with eosinophilic pneumonia	Serology Eosinophils in blood and sputum	May not be needed Albendazole (or ivermectin) in severe cases
Cestodes				
Hydatid cyst: <i>Echinococcus granulosus</i> and <i>E. multilocularis</i>	Worldwide (especially in sheep-rearing locales)	Pulmonary cyst; second most common site after liver; hemoptysis	Serology, Eosinophilia rare	Surgical, albendazole
Trematodes				
Paragonimiasis (Lung flukes): <i>Paragonimus westermani</i> , <i>P. africanus</i> , <i>P. caliensis</i> , <i>P. kellicotti</i> (US)	Southeast Asia, Central and South America, Africa; US	Pulmonary parenchymal invasion (larvae mature in lung) with cavitary lesions Hemoptysis	Eosinophilia Eggs in sputum or stool Serology	Praziquantel
Schistosomiasis: <i>Schistosoma mansoni</i> , <i>S. haematobium</i> , <i>S. japonicum</i> , <i>S. intercalatum</i>	Asia, South America, Africa	Hematogenous seeding with heavy infection Pulmonary hypertension	Eosinophilia Serology Stool ova and parasites	Praziquantel
PROTOZOA				
Amebiasis: <i>Entamoeba histolytica</i>	Worldwide; mostly tropical	Abscess Lungs 2nd most common extraintestinal site after liver Hemoptysis	Percutaneous aspiration Serology Antigen PCR	Metronidazole Tinidazole
Malaria: <i>Plasmodium</i> species (<i>falciparum</i> , <i>vivax</i> , <i>ovale</i> , <i>malariae</i> , <i>knowlesi</i>)	Africa, Asia, Central and South America	Interstitial opacities Acute respiratory distress syndrome	Blood smear Rapid diagnostic test	Antimalarial treatment; specifics depend on species and geographic distribution of drug resistance
Toxoplasmosis: <i>Toxoplasma gondii</i>	Worldwide; most common in immunocompromised, especially HIV-infected with CD4 < 100	Interstitial pneumonia usually associated with disseminated disease	Smear of bronchoalveolar lavage PCR Serology (cannot discriminate acute from past)	Pyrimethamine/sulfadiazine Pyrimethamine/clindamycin

Continued on following page

Table 39-1 Characteristics of the Most Common Parasites Causing Pulmonary Pathology (Continued)

Parasite	Distribution	Pulmonary Manifestation	Diagnosis	Treatment
Rarer Protozoan Pulmonary Parasite Syndromes				
Free-living ameba: <i>Acanthamoeba castellanii</i> or <i>A. polyphaga</i> , <i>Balamuthia mandrillaris</i> , <i>Naegleria fowleri</i>	Worldwide	Rare, usually immunocompromised; more frequently seen as central nervous system disease	Smear/tissue section	No highly effective treatment. Treatment varies according to species involved in the infection.
Babesiosis: <i>Babesia microti</i> , <i>Babesia divergens</i>	US, Europe	Interstitial opacities: acute respiratory disease syndrome	Blood smear, PCR, serology	Quinine/clindamycin Atovaquone/azithromycin
Cryptosporidiosis: <i>Cryptosporidium parvum</i> and <i>C. hominus</i>	Worldwide	Primarily gastrointestinal; respiratory syndrome and transmission proposed	Smear of bronchoalveolar lavage or sputum Stool ova and parasites	No highly effective treatment (nitazoxanide approved for children with diarrhea)
Leishmaniasis: <i>Leishmania donovani</i>	Africa, Central and South America	Interstitial pneumonia usually associated with disseminated disease	Smear or histopathology of tissue PCR, serology	Pentavalent antimonials Amphotericin B Pentamidine Miltefosine
Microsporidiosis (related to fungi): Many species	Worldwide; especially in immunocompromised	Interstitial pneumonia Tracheobronchitis	Chromotrope 2A stains of sputum, smears, or tissue	Albendazole Fumagillin
American trypanosomiasis: <i>Trypanosoma cruzi</i>	Central and South America	Interstitial pneumonia usually associated with disseminated disease	Serology, Blood smear, PCR	Nifurtimox Benznidazole

Serologic testing can be performed by enzyme-linked immunosorbent assay (ELISA), immunofluorescence, or Western blot. In general ELISA is most common in that there are standardized cut-off points and less operator variability.

Antigen tests can be performed by Western blot or ELISA designed to detect the antigen of choice.

PCR, polymerase chain reaction.

polymerase chain reaction (PCR) tests or other nucleic acid-based tests for specific parasites but these are often not routinely available. Rapid antigen tests for the diagnosis of malaria are approved and are becoming increasingly available. In some cases, specialized testing is available at the Centers for Disease Control and Prevention (CDC); the CDC website provides useful resources for diagnostic testing (<http://www.cdc.gov/dpdx/>), and the CDC provides access for certain medications that are not routinely available in the United States.

HELMINTHS

Helminths, or worms, cause the most common parasitic infections worldwide. They are classified into two major phyla: (1) nematodes, or round worms, include the major intestinal worms, and the filarial worms that cause lymphatic filariasis and onchocerciasis; (2) platyhelminths or flat worms include flukes (or trematodes), such as *Schistosoma*, and tapeworms (or cestodes). Helminths mainly infect rural and impoverished people, and chronic infection in children may be associated with growth stunting and long-term effects on health and cognitive function.² With the exception of *Strongyloides*, helminths do not have internal autoinfection cycles in the host, and disease is generally proportional to worm burden, as assessed by the number of eggs per gram of feces.

Helminths are a common cause of eosinophilic pneumonia, although the differential diagnosis of eosinophilic pneumonia includes other infectious and noninfectious

syndromes.³ (See also Chapter 68.) Helminth infections classically present with Loeffler syndrome, characterized by transient interstitial pulmonary opacities and eosinophilia that result when larval forms of helminths migrate through the lungs. These helminth infections are often accompanied by peripheral eosinophilia, bronchospasm, and elevated *immunoglobulin* (Ig) E levels. Larvae migrate through the lungs, up the respiratory tree and then are swallowed, thereby reaching the gastrointestinal tract. Because the larvae have not yet matured into egg-bearing adults, stool ova and parasite examinations may not be helpful during acute infection. Depending on the burden of infection, helminth infestation and the accompanying eosinophilic pneumonia may result in an asthma-like syndrome, or in pulmonary damage due to release of cytotoxic cationic proteins from eosinophil granules.⁴

NEMATODES

The parasitic nematodes (round worms) of humans that cause ascariasis, hookworm disease, trichinosis, and strongyloidiasis have a lower respiratory phase as part of their life cycles. In each, larvae migrate through the lungs in transit to the gastrointestinal tract. In most cases, this migratory phase is asymptomatic, but cough, substernal discomfort and wheezing may be accompanied by transient radiographic opacities and eosinophilia (Loeffler syndrome).

Ascariasis

Ascariasis caused by the nematode *Ascaris lumbricoides* is the most common human helminth infection and is

estimated to infect almost 1 billion people.² Although it has a worldwide distribution, ascariasis is most common in tropical and semitropical regions. Although highly prevalent, ascariasis is associated with chronic disability rather than death. An estimated 4 million people in the United States are infected,⁵ primarily children in rural areas of the southern United States. Humans are the only known host of *A. lumbricoides*, although the pig species *A. suum* is similar biochemically and morphologically. Females produce eggs that are shed in stool. The eggs mature in moist environments; humans are infected by swallowing ova that contaminate water, food, or soil. In regions where there are high worm burdens, infection can also be acquired by inhalation of ova. The eggs bear rhabditiform larvae that hatch in the intestine. The resulting larvae are released, burrow through the intestinal wall, and enter the hepatic circulation via capillaries and lymphatics. They then migrate via the right side of the heart into the lungs. The worms migrate up the bronchial tree, are swallowed, and make their way to the duodenum, where they mature into adults after several months. Once the worms reach the intestines, children may have nausea, vomiting, abdominal pain, and anorexia, reflecting high worm burdens that can lead to obstruction or chronic malnutrition.⁵ Adult worms can live in the human intestine for several years.

Clinical Features. Infected individuals, usually children, are typically asymptomatic. The most common symptoms are nonspecific abdominal complaints. However, some may experience malaise and fever with or without respiratory symptoms such as cough, chest pain, dyspnea, bronchospasm, and hemoptysis. Pulmonary symptoms develop 9 to 12 days after ingestion of eggs and can persist 2 to 3 weeks. This stage of the infection may be associated with leukocytosis and eosinophilia. Acute eosinophilic pneumonia resulting in respiratory distress and requiring intubation has been reported but is rare.^{6,7} In some regions of the world, pneumonitis is seasonal, due to climate conditions that favor transmission of ascariasis.⁸

Diagnosis. Chest imaging during the initial stage of infection may reveal transient unilateral or bilateral opacities (eFig. 39-1). The diagnosis is difficult to confirm during the acute stage, because ova do not appear in the stool until 2 to 3 months after infection. Peripheral eosinophilia may be detected, and larvae, eosinophils, or Charcot-Leyden crystals may be found in sputum or gastric contents.

Treatment. The treatment of choice for ascariasis is albendazole, although mebendazole and ivermectin are also efficacious against adult worms. Although the pulmonary phase is self-limiting, the persistent gastrointestinal phase warrants treatment to relieve symptoms and reduce transmission.

Hookworm Disease

Hookworm disease is caused by *Ancylostoma duodenale*, *Ancylostoma ceylanicum*, or *Necator americanus*. These helminths infect at least a half billion people worldwide,² primarily in tropical and subtropical regions. They reside in the small intestine where they attach to the mucosa and feed on blood and host tissue, causing iron deficiency

anemia as the major cause of morbidity. Unlike other helminths, hookworm prevalence increases with age, and there is no protective immunity.

Clinical Features. Hookworm ova are passed in the stools of an infected person, which then hatch into rhabditiform larvae that molt and become filariform larvae. Filariform larvae in the soil penetrate the skin of a human host; this can be associated with a pruritic rash. The larvae enter the lymphatics or venules and ultimately reach the pulmonary circulation. Some persons experience cough, bronchospasm, and transient pulmonary opacities with or without fever.^{9,10} Bronchitis and/or pneumonia may develop when the larvae break through capillaries and enter the alveolar spaces. Peripheral and pulmonary eosinophilia are common during this stage of infection.

Once the worms reach the intestine, an individual may have nonspecific gastrointestinal symptoms including nausea and abdominal pain. Iron deficiency anemia is the most important consequence of hookworm infection and can lead to cognitive problems. Malnutrition and hypoproteinemia can also complicate hookworm infection.

Diagnosis and Treatment. Stool examination reveals hookworm ova 2 to 3 months after pulmonary symptoms, but in cases of light infection, concentration of stool may be necessary to detect the ova. Diagnosis during the pulmonary phase is difficult and relies upon isolation of larvae from respiratory secretions, BAL fluid, or gastric secretions. The treatment of choice is albendazole (single dose) or mebendazole (twice daily for 3 days). These drugs kill the adult worms but are not effective against the pulmonary larval stages. Patients should be screened for ova in stools 1 month after treatment and, if ova are still present, retreatment is indicated to eliminate adults that developed after the initial treatment.

Strongyloidiasis

Although there are more than 50 species of *Strongyloides*, *Strongyloides stercoralis* is the most common in humans. This helminth has a worldwide distribution and is endemic in Latin America, south Asia, sub-Saharan Africa, the United States (especially the southern states and Appalachia), Europe, and Australia.¹¹ Up to 100 million people are estimated to be infected,¹² although some experts believe that the worldwide prevalence of *Strongyloides* infection may be much higher.¹³ Due to lack of awareness amongst clinicians and its prevalence in people in resource poor settings, *Strongyloides* infection is often undiagnosed or diagnosed late.

Strongyloides has a complex life cycle consisting of free-living and parasitic forms. Humans are the primary reservoir and acquire infection from soil or vegetation contaminated with human feces. Similar to hookworm infection, strongyloidiasis is initiated by penetration of the skin by infective filariform larvae, frequently through the soles of the feet. After penetration of the infective larvae through the skin or gut mucosa, they are carried via the circulation to the lungs and penetrate into alveoli and then ascend the tracheobronchial tree. The larvae are swallowed and reside in the small intestine where they ultimately develop into adult worms. Ova are released and hatch into rhabditiform

larvae, which are passed in feces. These larvae transform into filariform larvae. The larvae can also molt and transform into free-living adults in soil, where they may transform into infective filariform larvae. Some rhabditiform larvae may molt into filariform larvae while still in the small bowel and then invade the mucosa of the bowel or the perianal area. Filariform larvae that form internally can cause autoinfection in which they migrate through the circulation to the lungs, thereby recapitulating the early migratory phase.¹⁴ Infection can also take place through the mucosa of the lower gastrointestinal tract or the perianal area¹⁵ from larva that have transformed into infective filariform larvae in the gut.

Infection with *Strongyloides* results in a variety of clinical syndromes ranging from a mild disease to the hyperinfection syndrome seen in immunocompromised hosts.¹⁶ Cell-mediated immunity that develops after primary infection limits the extent of autoinfection, so larvae and adult worms largely remain confined to the intestine, where they can survive for decades in immunocompetent individuals. With immune suppression, especially caused by steroids, and other immunodeficient states, especially infection with human T-lymphotropic virus-1 (HTLV-1),^{16a} autoinfection can become pronounced and lead to hyperinfection.

Clinical Features. The clinical manifestations of strongyloidiasis depend on the intensity of infection and immunologic status of the individual. Acute infection is rarely symptomatic but pneumonitis can develop during the larval migration phase. More than 50% of patients with chronic infections are asymptomatic. Up to 75% of symptomatic patients have peripheral eosinophilia and elevated serum IgE levels; strongyloidiasis should be in the differential diagnosis of any person who presents with persistent eosinophilia.

Patients can present with abdominal pain, diarrhea, and weight loss.¹² Dermatologic symptoms include pruritus, urticaria, and skin eruptions including larva currens, which is manifest as linear streaks that can be seen on the trunk, thighs, and buttocks due to migrating larvae (Fig. 39-1). The common pulmonary manifestations in immunocompetent individuals are transient pulmonary opacities with productive cough, dyspnea, and bronchospasm. Chest radiographs range from normal to bilateral nonspecific opacities. Strongyloidiasis may cause asthma, and improve-

ment may follow eradication of the infection. Reactive arthritis, nephrotic syndrome, chronic malabsorption, duodenal obstruction, and hepatic lesions have also been associated with chronic strongyloidiasis. Patients from highly endemic areas who have asthma or chronic obstructive pulmonary disease with eosinophilia should always be screened for *Strongyloides* infection before instituting steroid therapy to avoid hyperinfection.

The *Strongyloides* hyperinfection syndrome develops due to accelerated autoinfection. Hyperinfection is usually observed in the setting of immunosuppression, especially when caused by high-dose corticosteroids¹⁶⁻¹⁹ although other immunosuppressive drugs and radiation therapy have also been implicated. Infection with human T-lymphotropic virus-1 markedly predisposes to hyperinfection; this is thought to be secondary to deficiency of T-helper 2 cells that normally contribute to control of helminths.^{16,20} In addition, immunosuppression associated with lymphoma, leukemia, malnutrition, organ transplantation, and HIV/AIDS predispose to *Strongyloides* hyperinfection (see eFig. 90-30), although some studies indicate the risk is not increased by HIV.^{16,21}

Strongyloides hyperinfection is characterized by prominent gastrointestinal symptoms, including abdominal pain, nausea, vomiting, diarrhea, and ileus. The lung is also an important target in patients with *Strongyloides* hyperinfection. As filariform larvae migrate through the lungs, they cause pneumonitis with cough, hemoptysis, and respiratory failure. As the larvae leave the lumen of the gastrointestinal tract and invade the intestinal mucosa, they may carry bacteria from the gastrointestinal tract, resulting in polymicrobial bacteremia, bacterial pneumonia, acute respiratory distress syndrome, and gram-negative bacillary meningitis.²² *Strongyloides* hyperinfection has also been reported to mimic accelerated idiopathic pulmonary fibrosis.²³ Mortality of disseminated strongyloidiasis can be as high as 90%.

Diagnosis. In *Strongyloides* hyperinfection, larvae, ova, and adult worms may be observed in sputum, urine, BAL fluid, and other body fluids (see Fig. 39-1, see eFig. 90-30C). Diagnosis of *Strongyloides* infection may be difficult if the parasite load is low, because the most common diagnostic test is based on detection of *Strongyloides* ova in stool samples (see Fig. 39-1). Recently developed serology assays

Figure 39-1 Strongyloidiasis. **A**, Larva currens in a patient with chronic strongyloidiasis. **B**, Filariform larva in a pulmonary biopsy specimen (arrow). **C**, Filariform (arrow) and rhabditiform (arrowheads) larval stages of *Strongyloides stercoralis* in the stool from a patient with hyperinfection syndrome. These were also found in the sputum. (**A** and **B**, from Herman Zaiman's "A Pictorial Presentation of Parasites" with permission of the American Society of Tropical Medicine and Hygiene.)

use ELISA or immunofluorescence to detect serum antibodies to *Strongyloides*. While ELISA is more sensitive than detecting ova in stool, the specificity of this test is suboptimal in regions where other nematodes such as filariae are endemic, because cross-reactive antibodies are common.²⁴ Eosinophilia is common during hyperinfection; lack of eosinophilia is often associated with a poor prognosis.^{16,25}

Treatment. Ivermectin is the treatment of choice and eliminates the worm in more than 90% of subjects;¹³ ivermectin is significantly more effective than albendazole.²⁶ Although ivermectin is usually prescribed as a 2-day course, treatment is usually extended and individualized for the hyperinfection syndrome, to ensure eradication.¹⁶ Human T-lymphotropic virus-1 coinfection is associated with a higher rate of treatment failure,²⁷ and some patients may require additional therapy to prevent recurrence. Combination treatment with ivermectin and albendazole has also been proposed in severe cases or in chronic infections with human T-lymphotropic virus-1 coinfection when ivermectin alone has failed. In hyperinfection cases where oral treatment cannot be absorbed or tolerated, the veterinary preparation of ivermectin has been administered subcutaneously.^{28,29} There is no reliable test to monitor for cure but many individuals have reversion or decline of IgG serologies with successful treatment.²⁴ All patients with *S. stercoralis* infection should be treated, because of the risk of autoinfection and dissemination.

Some experts recommend that patients from highly endemic areas have a screening serology for strongyloidiasis before (or at the time of) starting steroids or organ transplantation and, if seropositive, treatment is indicated to prevent the hyperinfection syndrome.

Tropical Pulmonary Eosinophilia

Tropical pulmonary eosinophilia (TPE) is a distinct clinical syndrome in patients from tropical areas endemic for lymphatic filariasis such as *Wuchereria bancrofti* or *Brugia malayi*.³⁰ Most cases have been described in India, Pakistan, Sri Lanka, Southeast Asia, parts of the African continent, and South America, especially Brazil and Guyana. TPE is now recognized in nonendemic areas, predominantly in immigrants; TPE is thought not to be a significant risk during a brief visit to an endemic area.

Filariae have five morphologic stages; humans are infected with third stage larvae transmitted by mosquitoes. Infective larvae molt twice and develop into adults that survive in a human host for up to 20 years. The first stage larvae, or microfilariae, are released into the circulation by female adult worms. *Wuchereria* and *Brugia* microfilariae circulate in the blood in a temporal pattern that coincides with the feeding habits of their mosquito vectors.

Clinical Features. TPE is seen predominantly (80%) in males, usually in middle age. The major clinical features of TPE include nocturnal paroxysmal cough and bronchospasm, low-grade fever, weight loss, and lymphadenopathy; some patients also have hepatosplenomegaly. Leukocytosis, marked peripheral eosinophilia, and elevated serum IgE levels are common, and sputum or BAL specimens often contain eosinophils. Pulmonary function tests reveal both restrictive and obstructive defects. Although TPE is caused by filaria, patients with TPE do not have detectable microfilaremia. The pathogenesis of TPE is poorly understood but is believed to represent a response to microfilariae that are trapped in the lungs.^{31,32}

Diagnosis. The diagnosis of TPE is based on the combination of clinical, radiologic, epidemiologic, and laboratory data, without the need for lung biopsy. Patients have nocturnal dyspnea with eosinophilia, elevated serum IgE, and a positive serologic test (ELISA) for antibodies to filarial antigens. Because the specificity of filarial serology tests is compromised by cross-reactivity with other helminths, other data are important for an accurate diagnosis.^{1,33} Chest radiographs usually reveal increased bilateral bronchovascular markings and reticulonodular opacities or diffuse miliary lesions, or opacities in the middle and lower lung fields (Fig. 39-2, eFig. 39-2). Cavitation, bronchiectasis, and pleural effusion have been reported but are uncommon; chest radiographs may also be normal. When pathological specimens have been obtained, eosinophilic infiltration of the interstitial and perivascular areas, eosinophilic abscess formation and eosinophilic granulomas can be observed, and worm fragments are occasionally found.³⁴ Electron microscopic examination of the lung has demonstrated degranulation of the eosinophils, implying that tissue destruction may be mediated by cytotoxic granule

Figure 39-2 Tropical pulmonary eosinophilia. **A**, Chest radiograph of a patient from Sri Lanka with confirmed tropical pulmonary eosinophilia shows subpleural right lung consolidation, subpleural left midlung opacity, and bilateral perihilar interstitial thickening. **B**, Chest radiograph of the same patient after treatment with diethylcarbamazine. Note the improved parenchyma.

proteins released by these cells. Fibrosis may be present if the course of the disease is prolonged.

Treatment. All patients should be treated because TPE can progress to chronic restrictive lung disease. Administration of diethylcarbamazine, an antihelminthic drug, results in improvement in the signs and symptoms of TPE, with reduced eosinophilia and serum IgE levels. Some experts have suggested ivermectin therapy either alone or in combination with diethylcarbamazine, although ivermectin has little effect on adult filariae and some patients require retreatment, regardless of the regimen. Recent studies have shown that doxycycline, which eliminates the bacterial (*Wolbachia*) endosymbiont of *W. bancrofti*, is efficacious in treatment of both adults and microfilaria of filariasis.³⁵ An endosymbiont is an organism that lives within another with mutual benefit; *Wolbachia* is thought to play an important role in the disease caused by *Wuchereria* and to its survival. It is proving a valuable target for many of the filarial diseases, especially because it can be targeted with doxycycline, which is better tolerated than diethylcarbamazine. Steroid therapy should be administered with caution because TPE and pulmonary strongyloidiasis have similar presentations and steroids may enhance the morbidity and mortality of strongyloidiasis.

Visceral Larva Migrants

Visceral larva migrans (VLM) is a clinical syndrome caused by infection of humans by the dog ascarid *Toxocara canis* or the cat ascarid *Toxocara cati* in temperate and tropical climates. Children acquire infection by ingesting embryonated eggs in contaminated soil or sandbox contents; a history of pica is common in infected children.³⁶ Although VLM usually afflicts children, adults have also been described with VLM. A VLM-like syndrome has also been reported as a result of infection with *A. suum*, the parasite of pigs,³⁷ and *Baylisascaris procyonis*, the raccoon ascarid.³⁸

Because the hatched larvae cannot mature into adults in humans (which are dead-end hosts), the larvae migrate throughout the visceral organs of humans causing an acute eosinophilic syndrome.

Clinical Features. *Toxocara* infection affects diverse organ systems.³⁹ Pulmonary manifestations are present in 80% of cases and include cough, shortness of breath, and wheezing, resembling asthma.⁴⁰ Although symptoms are usually mild, severe respiratory symptoms have been reported.^{41,42} These manifestations are a result of damage to the lung by the larvae and by immune responses to them.⁴³ Other manifestations may include urticaria, lymphadenopathy, hepatosplenomegaly, and seizures. Involvement of the central nervous system,⁴⁴⁻⁴⁶ eye, and myocardium^{47,48} have been reported but are not common.

Diagnosis and Treatment. The radiographic appearance in VLM is variable and includes bilateral or segmental and patchy opacities, which can be migratory; subpleural opacities may be detected by *computed tomography* (CT). Laboratory evaluation may reveal leukocytosis, marked eosinophilia, elevated anti-A or anti-B isohemagglutinin titers, and abnormal liver function tests; IgE levels are frequently elevated. The diagnosis is made by ELISA and

immunoblot testing. Because larvae do not mature to adults in humans, there are no ova in the stool.

Because VLM is a self-limited syndrome, antiparasitic drugs may not be required. However, if the symptoms are moderate or severe, albendazole is the drug of choice; diethylcarbamazine is an alternative therapy. In severe cases, adjunctive steroids may accelerate symptom resolution. Preventive measures include control of soil contamination, curbing pica, and regular deworming of dogs and cats.

Other Ascarids

Infection with *Baylisascaris procyonis*, an ascarid of raccoons, results in a systemic disease characterized by eosinophilia. Pulmonary involvement has been reported in this infection,³⁸ although the major clinical manifestations are neurologic and ocular. There is no proven therapy, although albendazole may be beneficial.

Dirofilariasis

Dirofilaria immitis, the dog heart worm, is an important cause of morbidity and mortality in dogs.⁴⁹ It is transmitted by mosquitoes, but humans are dead-end hosts. In the United States, most cases have been described in the Southeast. The worms migrate via the venous circulation and right heart where they reach the pulmonary arteries. In humans, the filariae are vascular parasites in the pulmonary artery, inducing vasculitis and formation of a pulmonary nodule upon death of the parasite (Fig. 39-3).⁵⁰ Chest radiographs usually reveal a well-defined homogeneous spherical or oval coin lesion with smooth edges. The majority of cases are asymptomatic, although some individuals may have cough and pneumonitis.⁵⁰ Eosinophilia is absent. Because there is no reliable noninvasive test for *Dirofilaria*

Figure 39-3 Dirofilarial infection in the lung. Chest radiograph showing a solitary nodule (arrows) in the lung from a patient with confirmed *Dirofilaria immitis*. (From McCall GW, Genchi C, Kramer LH, et al: Heartworm disease in animals and humans. *Adv Parasitol* 66:193-285, 2008.)

infection, nearly all cases require biopsy to establish the diagnosis. Surgery is both diagnostic and curative.

Trichinosis

Trichinosis is caused by the parasites of the genus *Trichinella*, especially *T. spiralis*; these are the only nematodes that occupy an intracellular location and that are acquired by ingestion of contaminated meat. Humans usually acquire the infection by ingesting cysts containing the coiled larvae in raw or partially cooked pork, pork products, or game. The larvae that emerge from the ingested cysts invade the small intestine.

Clinical Features. The enteral stage may be either asymptomatic or may be accompanied by signs and symptoms of gastroenteritis. During the ensuing parenteral stage, newborn larvae enter the bloodstream and circulate to various organs. However, they only encyst in peripheral skeletal muscle, forming the “nurse cell,” consisting of an infected myocyte fed by vessels formed by neoangiogenesis. Most symptoms are due to inflammation associated with the invasion of larvae through the intestine and with influx of eosinophils and mast cells in the region of nurse cells. During the acute stage of infection, common symptoms include malaise, abdominal pain, fever, nausea, vomiting, myalgias, and muscle weakness with facial and generalized edema. Respiratory tract involvement is uncommon but, in severe cases, there may be dyspnea and transient pulmonary opacities. Dyspnea may result from larval invasion of the diaphragm and the accessory muscles of respiration⁵¹; however, lung inflammation may also play a role.⁵²

Diagnosis and Treatment. Trichinosis is usually diagnosed based on clinical presentation, epidemiology, eosinophilia, and a positive ELISA.¹ Muscle biopsy is definitive but is not recommended because of low sensitivity. Treatment is with albendazole; corticosteroids may be added in severe cases, especially those with pneumonitis, myocarditis, or meningoencephalitis. It is unclear whether treatment alters the course of infection, particularly because it does not appear to affect worms after they have already encysted. Trichinosis is prevented by consuming meats that are fully cooked to a temperature of 140°F.

Gnathostomiasis

Gnathostomiasis is caused by helminths of the genus *Gnathostoma* and is endemic in South Asia and Southeast Asia, China, and Latin America, especially in cultures in which uncooked fish is consumed.^{53,54} *Gnathostoma spinigerum* is the most common agent of human gnathostomiasis. Humans are accidental hosts; cats and dogs are the definitive hosts. *G. spinigerum* has a complex life cycle involving two intermediate hosts.⁵⁵ Humans usually become infected with third-stage larvae by ingesting raw or inadequately cooked freshwater fish or other intermediate hosts such as snakes, frogs, and chickens. However, alternative routes of infection have also been suggested such as ingestion of water containing infected copepods and penetration of the skin of food handlers by third-stage larvae from infected meat.⁵⁴ The infective larvae released in the gut migrate to the liver and abdominal cavity and return to the stomach, where they are embedded in the wall, resembling a tumor

with an aperture communicating with the lumen to release eggs.⁵⁶ The mechanical damage of migrating larvae has been cited as the primary cause of symptoms. Migration of larvae through tissues results in characteristic hemorrhagic tracts, surrounded by eosinophilic infiltration. When the lungs are involved, patients present with cough, pleuritic chest pain, hemoptysis, lobar consolidation, lobar collapse, pleural effusion, pneumothorax, or hydrothorax. Subcutaneous swellings, unexplained eosinophilic pleural effusion, and peripheral eosinophilia are considered a clinical triad and should prompt consideration of gnathostomiasis.

Diagnosis and Treatment. Diagnosis of gnathostomiasis is based on the presence of eosinophilia, migratory inflammation, and history of exposure risk. The diagnosis can be confirmed by identification of the worm in tissue or by serology. The treatment of choice is albendazole or ivermectin.

TREMATODES

Paragonimiasis

The lung flukes of the genus *Paragonimus* encompass several species important in human disease. *Paragonimus westermani* is found in humans and animals in Asia, Africa, and South America. However, greater than 90% of the cases are seen in Asia; *P. westermani* is rarely contracted in the United States.⁵⁷ Most cases of paragonimiasis acquired in the United States are due to *Paragonimus kellicotti*^{55,58} after ingestion of crayfish. The parasite has a complex life cycle involving freshwater snails, crustaceans, and mammals.

Humans become infected by ingesting raw, partially cooked, or pickled crab or crayfish containing metacercariae, which excyst in the duodenum and penetrate the intestinal wall to enter the peritoneal cavity. Larval forms penetrate the diaphragm and enter the pleural cavity and lung parenchyma where they mature to adult worms. Pairs of adult worms live in cystic cavities near bronchial passages (Fig. 39-4) and produce eggs. Cystic cavities eventually rupture into a bronchiole, allowing eggs to be expectorated or swallowed and passed in feces.

Clinical Features. A minority of infected individuals have a symptomatic stage of acute infection approximately 2 weeks after exposure, marked by abdominal pain, diarrhea, fever, chest pain, cough, urticaria, peripheral eosinophilia, and elevated levels of IgE.⁵⁹ In contrast, most infections have an insidious onset with clinical manifestations 5 to 10 years following exposure. Symptoms of later stage infections include cough productive of thick, rusty-colored or bloody sputum with Charcot–Leyden crystals, with or without pleuritic chest pain.⁶⁰ There may be frank hemoptysis resembling that in tuberculosis.⁶¹ Fever and eosinophilia can be absent in chronic infections; a common finding is an abnormal chest radiograph in an asymptomatic patient (see Fig. 39-4).

Diagnosis. Chest radiographs may reveal a variety of lesions including focal involvement or consolidation. Cavitary lesions appear as the flukes mature and may measure up to 4 cm in diameter; small cysts and calcified or noncalcified nodules (eFig. 39-3) may be present. Pleural effusion,

Figure 39-4 *Paragonimus westermani*. **A**, Chest radiograph of a patient who presented with hemoptysis shows minimal perihilar linear and reticular opacities. **B**, Granuloma surrounding ova. **C**, Cross section of a pair of adults in the lung. **D**, Ovum in the sputum. (From Herman Zaiman's "A Pictorial Presentation of Parasites" with permission of the American Society of Tropical Medicine and Hygiene.)

pneumothorax, and pleural thickening may develop in a minority of patients.^{60,62} The pleural fluid characteristically contains leukocytes, many eosinophils, elevated concentrations of protein and lactate dehydrogenase, and low concentrations of glucose. Histopathologic examination of the lung reveals adult worms within fibrous cysts communicating with bronchi or bronchioles; granulomas may contain eggs at the center (see Fig. 39-4). Pneumonia, bronchiectasis, and vasculitis may be present. Acute and chronic pathologic changes may coexist within the same pulmonary lesions.

When the diagnosis of paragonimiasis is suspected, it can be confirmed by finding morphologically characteristic eggs in sputum, stool, gastric aspirates, or tissue (see Fig. 39-4). Bloody sputum is the most likely to yield positive results. ELISA and immunoblot assays that detect antibodies to *Paragonimus* antigens are offered by the CDC in Atlanta, Georgia.

Treatment. Praziquantel is the drug of choice. Untreated pulmonary paragonimiasis may resolve within 5 to 10 years (the life span of the adult worms) but chronic infection may be accompanied by extensive fibrosis. Paragonimiasis can be prevented by cooking crabs and crayfish fully before ingesting.

Schistosomiasis

Schistosomiasis is one of the most important parasitic infections of humankind. It is found in tropical and subtropical areas of the world including South America, Africa, the Middle East, and East Asia, including the Philippines.⁶³ The

World Health Organization estimates that more than 200 million people are infected worldwide.⁶⁴ Five species of schistosomes cause human disease: *Schistosoma hematobium*, *S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*. Infection is acquired when cercariae penetrate the skin during interaction with fresh water while bathing, wading, or doing laundry. After penetrating the skin, the cercariae lose their tails and quickly transform into juvenile forms (schistosomula) that migrate to the lung and liver. These transform into adults that mate and then travel to their tissue destination. *S. hematobium* are found in the venous plexus of the urinary bladder while *S. mansoni* and *S. japonicum* reside in mesenteric veins. Female worms lay eggs that are excreted either in the urine (*S. hematobium*) or feces (*S. mansoni*, *S. japonicum*). Adult schistosomes may live and produce eggs for as long as 30 years.

Clinical Features. A skin reaction (erythematous raised 1- to 3-cm lesions) may develop within hours (and as late as 1 week) after cercarial penetration in those infected for the first time. In some previously unexposed persons, acute schistosomiasis, known as Katayama fever, develops after heavy exposure to *S. japonicum* or *S. mansoni*.^{65,66} Symptoms usually develop between 4 and 8 weeks after exposure, which coincides with maturation of adults and the beginning of egg laying. Acute schistosomiasis is characterized by urticaria, fever, chills, cough, wheezing, headaches, lymphadenopathy, hepatosplenomegaly, peripheral eosinophilia, and elevated serum IgE levels. This acute phase usually resolves within several weeks but can lead to death in rare instances.

Figure 39-5 Schistosomiasis of the lung. **A**, Chest CT showing macronodules with ground-glass halo (arrows). **B**, Granuloma in the lung surrounding a *Schistosoma* ovum. (**A**, From Weber-Donat G, Donat N, Margery J: Acute pulmonary schistosomiasis: computed tomography (CT) findings. *Am J Trop Med Hyg* 82:364, 2010; **B**, from Herman Zaiman's "A Pictorial Presentation of Parasites" with permission of the American Society of Tropical Medicine and Hygiene.)

The major pathologic findings in schistosomiasis in any organ are granulomas surrounding eggs⁶⁷ (Fig. 39-5). Chronic pulmonary schistosomiasis may be the result of deposition of eggs in pulmonary vessels followed by granuloma formation and obstruction of blood flow.⁶⁸ However, vasospasm and inflammation also contribute to the pulmonary findings.⁶⁹ Chronic pulmonary hypertension develops in approximately 5% of patients with hepatosplenic schistosomiasis, usually after many years of untreated infection.^{70,71}

Diagnosis and Treatment. Chest radiographs of patients with acute symptoms may show diffuse pulmonary opacities or nodules with indistinct borders, which on CT may have a ground-glass "halo" appearance (see Fig. 39-5A).⁷² Pleural effusions and thoracic lymphadenopathy may also be present in acute schistosomiasis. Imaging in chronic pulmonary schistosomiasis reveals nodules, miliary lesions, and cavitory lesions.

Diagnosis of schistosomiasis is made by stool or urine examination or rectal biopsy, although shedding of eggs usually does not commence until 6 weeks after exposure.⁷³ Nearly all patients with symptomatic acute schistosomiasis have eosinophilia and elevated serum IgE levels. ELISA and immunoblot assays that detect antibodies to schistosome antigens are available, but these tests may be negative in acute infection and may remain positive years after treatment. Lung biopsies may reveal granulomas surrounding eggs (see Fig. 39-5B).

The treatment of choice for schistosomiasis is praziquantel. Praziquantel kills adult worms but may not kill immature parasites. In some cases, symptoms can transiently worsen after treatment; this is presumed to be due to release of proinflammatory components of dead parasites. Pulmonary hypertension due to schistosomiasis can also worsen with antiparasitic treatment.

CESTODES

Echinococcosis

The cestode *Echinococcus granulosus*, the dog tapeworm, has a scattered worldwide distribution. It remains an important public health problem in the Mediterranean basin where it is especially common in Italy, Spain, Albania, and the countries of the former Yugoslavia. *E. granulosus* is also found

throughout Central America and South America and in scattered areas of sub-Saharan Africa, China, Russia, and the countries of the former Soviet Union. *Echinococcus multilocularis*, the fox tapeworm, is endemic in Canada, parts of the United States, central Europe, the countries of the former Soviet Union, China, and northern parts of Japan.⁷⁴⁻⁷⁶

The adult tapeworm (Fig. 39-6) usually infects canines and sheds millions of eggs. The ova are excreted in feces, and intermediate hosts, including humans, become infected when they ingest the ova in contaminated food or water. In most areas, dogs are the definitive hosts, and sheep are the main intermediate hosts. Larvae are released from ova after ingestion and migrate via the bloodstream or lymphatics to various organs, usually the liver and lung, but kidney, bone, and brain may also be involved. The larvae mature into cysts and, in the case of *E. granulosus*, the cyst is fluid-filled and unilocular, consisting of an inner germinal layer and an outer acellular laminated layer. Daughter cysts may arise from the inner layer and there is an outer layer composed of fibrous tissue, which is host-derived and is also called a pericyst. While *E. granulosus* is more common in humans, *E. multilocularis* is usually more pathogenic.

Clinical Features. The lungs are involved in 20% to 40% of cases of cystic echinococcosis; the liver is involved in 50% to 70%.⁷⁷ Cystic echinococcosis usually presents as a solitary cyst involving one organ, usually the liver or lung; 10% to 15% of individuals have more than one organ involved. In children, the lungs are involved more often than the liver.⁷⁸

Pulmonary echinococcosis is commonly discovered as an incidental finding on chest imaging (eFig. 39-4). In symptomatic patients, the clinical manifestations of pulmonary echinococcosis are most often the consequence of cyst rupture; less frequently, symptoms are due to compression by an enlarging cyst. Rupture of an echinococcal (hydatid) cyst into a bronchus results in fever and cough, which can have an abrupt onset. In some patients, the sputum can contain macroscopic fragments of the parasite. Ruptured cysts that communicate with an airway can become secondarily infected by bacteria and/or fungi. Rupture of a hydatid cyst into the pleural space can be associated with hypersensitivity responses, including fever, urticaria, and wheezing; frank anaphylaxis can also develop, but is rarely fatal. Rupture into the pleural space can also cause

Figure 39-6 Echinococcal cysts. **A**, Adult *Echinococcus granulosus*. **B**, *Echinococcus* cyst of the liver near the diaphragm. **C**, *Echinococcus* cyst of the lung. **D**, Ruptured *Echinococcus* cyst of the lung with the “water lily” sign. (**A** and **D**, From Herman Zaiman’s “A Pictorial Presentation of Parasites” with permission of the American Society of Tropical Medicine and Hygiene; **C**, courtesy Dr. Saul Santivanez, Lima, Peru.)

empyema, with or without bacterial superinfection. Cysts that enlarge without rupturing may erode into adjacent structures and cause bone pain, hemorrhage, or airway compression.⁷⁹

Diagnosis and Treatment. Diagnosis of pulmonary echinococcosis depends on the combination of imaging, serology, and microscopy. On chest radiographs, uncomplicated (unruptured) hydatid cysts appear as homogeneous oval or round masses 1 to 20 cm in diameter with smooth borders and normal adjacent lung tissue (see Fig. 39-6C; see eFig. 39-4). If a cyst ruptures into a large airway, partial discharge of the cyst contents results in an air-fluid level. A hydatid cyst that is completely emptied of liquid contents and collapsed can exhibit a “water lily” sign (see Fig. 39-6D), which is pathognomonic of a collapsed cyst but is rare. The water lily sign is created when air enters the cyst, allowing detachment of the inner endocyst from the outer pericyst, so that the endocyst collapses to float on the fluid in the partially filled pericyst, creating the appearance of a water lily floating on a pond. CT scans may allow distinction of hydatid cysts from other pulmonary cysts by revealing the presence of daughter cysts within a larger cyst. Cardiac echinococcosis and pulmonary embolization of organisms are rare (eFig. 39-5).

Serology testing for echinococcosis currently consists of an ELISA that detects antibodies to a cyst antigen. Although the assay is quite sensitive in patients with hepatic involvement, the sensitivity in patients with pulmonary echinococcosis is approximately 50%. An additional limitation of the current assay is that there may be cross-reactivity if a

patient has another tissue helminth infection, especially cysticercosis. As a consequence of the suboptimal sensitivity and specificity, the results of echinococcus serology testing must be interpreted in the context of other clinical and radiographic evidence.

If the cyst ruptures, cyst fragments, especially the rigid mouthparts (scolices) of the parasite, may be detected by microscopic examination of sputum or pleural fluid.

Treatment. Surgical removal is the principal therapeutic approach in patients who can tolerate the procedure. The surgical approach must be planned to minimize the likelihood of intraoperative cyst rupture, in that release of the contents can result in anaphylaxis and in dissemination of the parasites, with subsequent relapse. Preoperative administration of albendazole is recommended, to reduce the consequences of dissemination.⁷⁹ Praziquantel is often added if a cyst ruptures because it has a scolicidal effect. Intraoperative administration of a helminthicide agent such as hypertonic saline or 1% formaldehyde, left in place in the cyst lumen for 15 minutes or more before further manipulation, is also thought to minimize the consequences of spillage of cyst contents.⁷⁹⁻⁸¹

In patients with symptomatic or complicated echinococcal cysts who cannot tolerate a thoracic surgical procedure, prolonged treatment with an antihelminthic may improve symptoms but is likely to be curative in only a minority of cases. Albendazole is currently the drug of choice; praziquantel also has activity, and the combination of albendazole and praziquantel may have greater efficacy than either drug alone. Monitoring responses to drug treatment must

be based on clinical findings and imaging procedures; serial serologic assays have been found to be without value.

Echinococcus multilocularis

Alveolar echinococcosis caused by *E. multilocularis* is a rare but potentially fatal disease. Wild canines are the definitive hosts and small animals are the intermediate hosts. The liver is the initial target of this parasite and the incubation period can be exceedingly long. It can spread to the lung as a result of metastatic dissemination or by direct extension through the diaphragm of a liver cyst with rupture into the thorax. *E. multilocularis* can involve the bronchial tree, pleural cavity, and mediastinal structures. The diagnosis is made by serology and biopsy. The only cure is radical resection followed by long-term therapy with albendazole. If not amenable to surgery, life-long treatment with albendazole may be beneficial.

PROTOZOA

Protozoa are unicellular eukaryotic organisms and are acquired by ingestion or by the bite of a vector. Gastrointestinal or systemic symptoms generally predominate in protozoal infections, although pulmonary symptoms can also be prominent.

AMEBIASIS

Amebiasis, caused by *E. histolytica*, is one of the most common parasitic diseases of humans. Although it predominantly affects individuals who live in Mexico, Central and South America, Africa, and the Indian subcontinent, travel and immigration have globalized this infection. *E. histolytica* is estimated to cause 40,000 to 100,000 deaths yearly,⁸² and it is estimated that 500 million people worldwide are infected with *Entamoeba*,⁸² although many are infected with nonpathogenic *Entamoeba dispar* rather than pathogenic *E. histolytica*.

E. histolytica does not involve intermediate hosts and has a simple life cycle, alternating between environmentally hardy cysts and invasive trophozoites. Although trophozoites are passed in bloody diarrhea, these forms cannot survive in the environment and are not transmitted to new hosts. Trophozoites can also survive in the intestine of asymptomatic carriers; some trophozoites differentiate into cysts in the intestine, which are then passed and serve as the source of transmission to new hosts. Cysts have a chitinous cell wall that enables them to persist in the environment for weeks to months and to infect subsequent hosts that ingest contaminated food or water. In 4% to 10% of individuals infected with *E. histolytica*, trophozoites invade the intestinal mucosa to cause intestinal disease. In others, the trophozoites enter the bloodstream and can establish infection in the liver, brain, or lungs.^{83,84}

Clinical Features. Intestinal amebiasis is associated with abdominal pain, tenesmus (constant urge to defecate), and diarrhea, which may be bloody, mucoid, or watery. Fever may be present but is not typical, and the onset of symptoms may be gradual with patients presenting with several weeks of symptoms. The course of intestinal

amebiasis can be fulminant, with ileus and intestinal perforation.

The most common site for extraintestinal amebiasis is the liver (eFig. 39-6); a smaller proportion of cases affect the lungs. Amebic brain abscesses are seen rarely. The typical patient with an amebic liver abscess is an adult male who has acquired the infection in an endemic area and presents with fever and right upper quadrant pain without intestinal symptoms. Although amebic colitis affects children and adults of both sexes, amebic liver abscesses are approximately 10-fold more common in men than women; the reason for this sex difference is unknown but is not due to differences in rates of infection.⁸⁵ Mouse models of amebiasis also demonstrate differences in host immune response between females and males.⁸⁶ Many patients presenting with extraintestinal amebiasis do not have cysts or trophozoites in the stool. A prior amebic abscess or amebiasis does not confer immunity to recurrence.

The extraintestinal manifestations of amebiasis can present years after leaving an endemic area.⁸² The lung is the second most common extraintestinal site of *E. histolytica* infection and usually results from the extension of a right lobe hepatic abscess, so patients may have right upper quadrant abdominal pain as well as pulmonary symptoms. Pleuropulmonary amebiasis complicates amebic liver abscess in 7% to 20% of cases,² although the chest radiograph is abnormal in nearly 50% of cases. Although any lobe of the lungs can be affected, the right lower lobe is most commonly involved,⁸⁷ and pulmonary amebiasis can be confused with bacterial pneumonia (see eFig. 33-27).⁸² Findings can include an elevated right hemidiaphragm, right pleural effusion, right lobe atelectasis, pulmonary consolidation with abscess formation, and hepatic-bronchial fistulas. Additionally, an empyema may develop from rupture of a liver abscess into the pleural space.⁸⁸ An occasional patient may present with shortness of breath⁸⁹ or rarely with respiratory failure⁹⁰ or the expectoration of “anchovy-paste” like sputum, which represents contents of an amebic abscess.⁹¹ Rarely, pulmonary amebiasis results from hematogenous spread without liver abscess. Hepatic abscesses can also rupture into the pericardium and cause cardiac tamponade.^{88,92,93}

Diagnosis. Molecular studies have shown that human *Entamoeba* consists of the virulent species *E. histolytica* and a nonpathogenic commensal species, *Entamoeba dispar*. Both *E. histolytica* and *E. dispar* species are frequently present in stool samples; the trophozoites are indistinguishable, although antigen and PCR assays discriminate between the species.⁹⁴ Serology tests are highly sensitive for diagnosis of extraintestinal amebiasis, but they may remain positive for years after an infection. Therefore, serology may not distinguish between current and past infection. In cases of known or suspected pulmonary involvement in amebiasis, CT scanning of the lung and adjacent liver should be used to define the extent of involvement and presence of fistulae (see eFig. 33-27).⁹⁵

Treatment. Patients with liver abscesses can usually be managed medically without percutaneous aspiration, but pleural or pericardial effusions⁸⁸ should be drained and larger lesions (>300 mL) may improve more quickly if drained.⁹⁶

The current medical treatment of choice is systemic metronidazole 750 mg three times daily for at least 10 days, monitoring clinical findings carefully. Monitoring responses with repeated imaging procedures is not generally necessary, and it is not unusual for the radiographic appearance to worsen before improvement.⁹⁵ Another nitroimidazole, tinidazole, is an alternative and has efficacy and toxicity similar to that of metronidazole. Agents such as paromomycin and diloxanide furoate that kill cysts in the intestine are not effective against extraintestinal amebiasis. After tissue invasive amebiasis has been treated with metronidazole or tinidazole, most experts recommend a course of diloxanide or paromomycin to eradicate cysts that may serve as sources of transmission or relapse.⁸² Because of the potential for asymptomatic infection to develop into dysentery or extraintestinal disease, or to be transmitted, all *E. histolytica* infections should be treated.

MALARIA

Human malaria is an acute systemic infection caused by *Plasmodium falciparum*, *P. vivax*, *P. malariae*, *P. ovale*, or *P. knowlesi*. *P. falciparum*, the most lethal human malaria, was estimated by the World Health Organization to cause 550 million cases per year in 2010. *P. vivax*, the second most common human malaria, is thought to cause 80 to 300 million cases. Recently, *P. knowlesi*, a simian malaria seen in Southeast Asia, has been associated with zoonotic malaria infections in humans.⁹⁷ Because this species resembles *P. malariae* morphologically, the parasite was mistaken for *P. malariae*, but *P. knowlesi* malaria has a more virulent course than *P. malariae* malaria and is more often fatal.

The World Health Organization estimated that in 2010 there were 660,000 deaths due to malaria, primarily in children infected with *P. falciparum* in sub-Saharan Africa. Although many cases of malaria are mild, severe malaria, including cerebral malaria, is still seen in many areas of the tropical and subtropical world and among travelers and immigrants in nonendemic areas. Most fatalities in the developed world are due to delayed diagnosis because either patients or clinicians are unaware of the risk of severe malaria.

Plasmodium species are transmitted by the bite of the female *Anopheles* mosquito. Sporozoites injected into the bloodstream traffic to the liver and initiate the clinically silent hepatic phase, which results in the release of thousands of merozoites that infect erythrocytes. The erythrocytic stages are responsible for clinical disease, and severe malaria includes anemia, coma, and respiratory failure; these are most frequent with *P. falciparum* infection.

The pathogenesis of severe malaria is not completely understood, but is thought to be caused by inflammatory mediators such as cytokines and chemokines and by vascular leukocyte adhesion molecules. *P. falciparum* elaborates a family of variant antigens that enables infected erythrocytes to adhere to microvascular endothelium.⁹⁸ Sequestration of infected erythrocytes in tissue microvessels is thought to be critical for pathogenesis of the most severe manifestations of malaria including cerebral malaria.⁹⁹ There is no sterile immunity to malaria, and malaria has exerted a profound selective pressure upon human evolution. Nearly all genetic erythrocyte defects, including sickle

cell anemia, thalassemia, pyruvate kinase deficiency, are most prevalent in regions of the world with high malaria prevalence and some, including heterozygous HbS, protect from severe malaria.¹⁰⁰

Clinical Features. Severe malaria is associated with fever, chills, anemia, thrombocytopenia, jaundice, and renal failure. The severity of symptoms is proportional to the parasite burden, and without treatment, *P. falciparum* malaria can progress within days to cause multiorgan failure, especially in nonimmune patients. The fevers of malaria are associated with the lysis of infected erythrocytes, and fevers are classically periodic (every 2 days for *P. falciparum*, *P. vivax*, and *P. ovale*; every 3 days for *P. malariae*) and nocturnal. However, this is not a reliable clinical sign, particularly for *P. falciparum*. *P. knowlesi* has a 24-hour cycle in erythrocytes and can be associated with rapid clinical deterioration and death.

Both *P. falciparum* and *P. vivax* are associated with systemic symptoms including pulmonary symptoms. Patients with malaria may present with cough and minimal involvement of the lung or with severe symptoms and signs of acute lung injury and acute respiratory distress syndrome.¹⁰¹ Chest radiographs may reveal bilateral opacities and lobar consolidation and pleural effusions, and alveolar macrophages may contain hemozoin, a brown degradation product of hemoglobin produced by the parasite. Bronchiolitis and pneumonia have been reported in the setting of *P. vivax* infection.¹⁰² Patients in coma as a result of cerebral malaria may be susceptible to aspiration pneumonia, and may require antibiotic therapy. Noncardiogenic pulmonary edema may develop in patients with severe malaria with any species of *Plasmodium*, even after several days of anti-malarial therapy.

Children, pregnant women, and nonimmune travelers to endemic areas are most susceptible to pulmonary complications (Fig. 39-7). The pathogenesis of the noncardiogenic pulmonary edema is unclear. Increased permeability of the alveolar capillaries appears to be an important mechanism by which the liquid fills the alveolar space, and pulmonary edema may be aggravated by fluid overload. The mortality rate of severe falciparum malaria is high.

Figure 39-7 Malaria. Diffuse bilateral symmetric lung opacities resembling pulmonary edema in a child with malaria.

Diagnosis. The diagnosis of malaria is most often made by examination of a blood smear. Thick blood smears are used to determine whether parasites are present, while thin blood smears are used by experienced technicians to identify the *Plasmodium* species by morphology. For *P. falciparum*, the most lethal human malaria, only the immature ring forms are detectable in the peripheral blood, so initial malaria smears may be negative. Mature intraerythrocytic forms of *P. falciparum* cause infected cells to adhere to the microvasculature and are thus rarely evident in peripheral blood. The presence of mature *P. falciparum* forms in the blood and high parasitemia (>10% of erythrocytes containing parasites) are signs of severe disease. *P. vivax* infects only reticulocytes, so parasitemias are lower than with *P. falciparum*. Because initial malaria smears may be negative, a smear should be repeated after 8 hours, and empirical treatment begun if the patient is seriously ill.

Rapid diagnostic tests that detect *P. falciparum* and *P. vivax* malaria antigens are available as point-of-care diagnostic tests. Because antigen can persist, these tests do not reliably discriminate current from very recent infection.

Treatment. Supportive care in addition to specific antimalarial therapy is extremely important, especially in the case of noncardiogenic pulmonary edema. The treatment of malaria is dependent on the species and the geographic area of the world where it was contracted. While *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi* can be treated with chloroquine, *P. falciparum* is nearly universally resistant to chloroquine. Intravenous artesunate, available from the CDC, is the treatment of choice for patients with pulmonary manifestations of malaria, which usually signifies severe malaria.¹⁰³ Artesunate has been reported to clear parasitemia more rapidly than intravenous quinine but, if artesunate is not available, intravenous quinidine or quinine should be used. Artesunate resistance has been detected in *P. falciparum* with increasing frequency, especially in Southeast Asia, and is manifest by slower clearance of parasitemia, thus requiring a longer duration of treatment to achieve cure.^{103a} Careful attention to fluid balance is required to maintain adequate end organ perfusion and prevent respiratory insufficiency due to fluid overload. Correction of hypoglycemia and attention to oxygenation is critical and, with high parasitemias, exchange transfusion may be attempted, although the clinical benefit of exchange transfusion has not been established. Severe malaria may also be complicated by concurrent pneumonia or bacterial sepsis that must be managed with appropriate antibiotics.

Once the patient improves, there are a variety of choices for oral treatment. *P. vivax* and *P. ovale* treatment regimens should include primaquine to eliminate hypnozoite forms within the liver, after determining the patient's G6PD status.

All travelers to malaria endemic regions are advised to take antimalarial prophylaxis and use insecticide-treated bed nets to prevent malaria, but a history of malarial prophylaxis does not rule out malaria and some travelers who have taken prophylaxis either have subtherapeutic levels of drug or have acquired resistant organisms. Although there are ongoing trials investigating malaria vaccines, thus far there is no clinically approved malaria vaccine. Clinicians seeking help for diagnosis or treatment of malaria should

call the CDC Malaria Hotline 770-488-7788 or 855-856-4713 toll free, with further information available at www.cdc.gov/malaria/.

TOXOPLASMOSIS

Toxoplasma gondii is a ubiquitous Apicomplexa protozoan parasite of mammals and birds. *T. gondii* does not require passage through its definitive host and thus can propagate clonally through its intermediate hosts. Intermediate hosts pass *T. gondii* latent bradyzoites within cysts that can initiate infection in new hosts that ingest the cysts in raw or undercooked meat. Cats are the definitive hosts and oocysts shed in cat feces are highly infectious, providing a source for contamination of food and water. In humans, new infection in a previously naive mother can lead to congenital toxoplasmosis, but vertical transmission from a previously exposed mother to her child is very rare, with only a few isolated reports of women who were infected before pregnancy.¹⁰⁴ The prevalence of infection, as assayed by seropositivity, varies with geography, and ranges from 10% to 90%.

T. gondii causes congenital infections in immune competent hosts and opportunistic infections in immunocompromised hosts, including individuals with AIDS (see Chapter 90).¹⁰⁵ *T. gondii* has a predilection for the central nervous system, where it causes necrotizing encephalitis, and for the eye, where it causes chorioretinitis. Although it disseminates throughout the body, CNS or ocular disease is most common. The development of clinically apparent toxoplasmosis is usually a consequence of reactivation of bradyzoites found within tissue cysts into actively replicating tachyzoites.¹⁰⁶⁻¹⁰⁸

Clinical Features. In most cases of pulmonary toxoplasmosis, pulmonary disease is part of multisystem disease in an immunocompromised host such as in persons with HIV/AIDS (CD4 T cells < 50/μL^{109-111a}), in patients with hematologic malignancies, and in organ transplant recipients.¹¹²⁻¹¹⁵ Pulmonary toxoplasmosis may rarely develop in immunocompetent persons where it may resemble atypical pneumonia.¹¹⁶ Clinical symptoms include fever, cough, and shortness of breath.¹⁰⁹⁻¹¹¹ A more fulminant pneumonia associated with acute toxoplasmosis has been seen in South America where highly virulent strains of *T. gondii* have caused "Amazonian toxoplasmosis," presenting as severe disseminated systemic disease.¹¹⁷

Diagnosis. Chest radiographs reveal bilateral diffuse opacities and/or nodular bilateral opacities that may be confused with *Pneumocystis* pneumonia.¹⁰⁹⁻¹¹¹ Examination of the sputum or fluid from BAL may reveal organisms that stain with Giemsa.¹¹⁸ Pleural fluid, if present, may contain tachyzoites.¹¹⁹ PCR-based molecular techniques are also available if the parasite is suspected but cannot be found by staining. At autopsy, the lungs are congested and hemorrhagic with areas of consolidation. Histopathologic examination reveals an interstitial pneumonitis and alveolar damage. A frank necrotizing pneumonia may also be observed, with many extracellular and intracellular tachyzoites. Nearly all patients with toxoplasmosis are seropositive, and a negative serologic test suggests another

diagnosis. Rarely, primary infection can present as disseminated disease, and serologies may be negative.

Treatment. The treatment of choice for toxoplasmosis is pyrimethamine and sulfadiazine with leucovorin (to prevent bone marrow toxicity), but there are several alternatives, including pyrimethamine and clindamycin with leucovorin. Although pyrimethamine and sulfadiazine are considered the treatment of choice, trimethoprim/sulfamethoxazole is active against *T. gondii* and has been suggested as primary therapy in resource poor areas due to its low cost.¹²⁰

OTHER PROTOZOA

Several other protozoa have been reported to be associated with pulmonary manifestations. Some of the more common parasites that can occasionally present with pulmonary disease are discussed here. Many of these have been increasingly reported, presenting as disseminated disease involving multiple organs, including the lungs, in association with HIV infection or other immunocompromised states.¹²¹ In addition, *Cyclospora cayetanensis*, *Trichomonas vaginalis*, *Trichomonas tenax*, *Trichomonas hominis*, and *Balantidium coli* have been reported to present with pulmonary disease.¹²¹

Babesiosis

Babesia are intraerythrocytic protozoan parasites.^{122,123} *Babesia microti* is carried and transmitted by the tick *Ixodes scapularis*. *B. microti* is found in Massachusetts, New York, Rhode Island, Connecticut, New Jersey, and the upper Midwest. In Europe, babesiosis is rarer but more frequently lethal, and is associated with *Babesia divergens*. Blood transfusion is another mode of transmission. The onset is usually gradual with malaise, fever, chills, sweats, and myalgias. Nausea, vomiting, headache, and psychiatric problems are also reported. There may be splenomegaly, anemia, thrombocytopenia, a normal or low white blood cell count, mild elevation of hepatic enzymes, and evidence of hemolysis. The major pulmonary complication is noncardiogenic pulmonary edema.^{124,125} As in malaria, the etiology of noncardiogenic pulmonary edema is not well understood. Parasitemia may range from less than 1% to more than 20% in persons with an intact spleen. Asplenic and immunocompromised patients often have more severe disease, including jaundice, renal failure, pancytopenia, high level parasitemia, shock, and disseminated intravascular coagulation.

Diagnosis. Diagnosis of babesiosis is made by the identification of the parasitized red blood cells on blood smears revealing a “Maltese cross” appearance. IFA-based serologic tests for *Babesia* have also been developed, but the high rate of seroprevalence in endemic regions limits the usefulness of these tests. Blood can be injected into a hamster for verification of active infection, and there are PCR-based diagnostic tests available that may be deployed for blood screening.¹²⁶

Treatment. Treatment of babesiosis is with quinine and clindamycin or azithromycin and atovaquone.¹²⁷ There have been reports of immunocompromised persons devel-

oping possible resistance to azithromycin and atovaquone after multiple treatments.¹²⁸

Cryptosporidiosis

The genus *Cryptosporidium* comprises several species widely distributed in animals including birds, cattle, and sheep. *C. parvum*, *C. hominis*, and *C. meleagridis* most commonly infect humans and are acquired by the ingestion of oocysts via water or food.

The most common clinical manifestation of cryptosporidiosis is watery diarrhea, which is self-limiting in immunocompetent hosts but chronic in immunocompromised hosts. In those with HIV/AIDS, diarrhea may be persistent, and may be massive and fatal.¹²⁹ Extraintestinal manifestations of cryptosporidiosis are observed most frequently in immunocompromised individuals. *Cryptosporidium* involvement of the lower respiratory tract is most common in patients with HIV/AIDS but can also develop in patients with other conditions.¹³⁰⁻¹³² Common symptoms include cough, fever, and shortness of breath; there may also be respiratory insufficiency.

Although the mechanism by which *Cryptosporidium* colonizes the respiratory tract is not clear, aspiration and hematogenous spread from the intestinal tract have both been suggested.¹³³ Chest radiographs are consistent with interstitial pneumonitis. Alveolar damage and interstitial fibrosis and hyperplasia of type II pneumocytes have been found at autopsy of patients with pulmonary cryptosporidia.¹³³

A recent study of HIV-negative Ugandan children with *Cryptosporidium* diarrhea and cough or other respiratory symptoms revealed that 17 of 48 (35.4%) had *Cryptosporidium* in their sputum,¹³⁴ suggesting that *Cryptosporidium* may cause more pulmonary disease than previously suspected, and that respiratory transmission is possible.

Diagnosis. Cryptosporidia can be detected in stool or respiratory samples by a modified acid-fast stain or by immunofluorescence.

Treatment. Nitazoxanide is efficacious and is approved for treatment of cryptosporidiosis in immunocompetent children and adults.¹³⁵⁻¹³⁷ Nitazoxanide is not efficacious in immunodeficient individuals with cryptosporidiosis; azithromycin and paromomycin have been associated with improvement in some patients, but clinical trials have not confirmed their efficacy in immunodeficient adults.

Free-Living Ameba

Four genera of free-living ameba infect humans: *Naegleria*, *Acanthamoeba*, *Balamuthia*, and *Sappinia*.¹³⁸ Infections with these species are rare but worldwide. *Naegleria* and *Acanthamoeba* are commonly found in lakes, swimming pools, tap water, and air conditioning units. *Acanthamoeba* sp are usually associated with granulomatous skin lesions and corneal ulcers. In immunocompromised patients, *Acanthamoeba* sp and *Balamuthia mandrillaris* may cause subacute or chronic granulomatous encephalitis accompanied by respiratory symptoms, nodular opacities, consolidation, and respiratory failure. In those patients, parasites have been recovered from BAL; organisms can also be detected in lung tissue (Fig. 39-8). *Naegleria fowleri* is associated with primary amebic meningoencephalitis that is acute and

Figure 39-8 Acanthamoeba of the lung. **A**, Silver stain showing *Acanthamoeba* (arrows). **B**, PAS stain showing the organism (arrow). (**A**, From Herman Zaiman's "A Pictorial Presentation of Parasites" with permission of the American Society of Tropical Medicine and Hygiene; **B**, courtesy Dr. Govinda S. Visvesvara.)

usually lethal. A PCR-based assay to identify ameba species in clinical samples is available from the CDC.¹³⁹ The mortality of these infections is high, and there are no antimicrobial agents with proven efficacy.

Leishmaniasis

Leishmania spp are found in Asia, Africa, Central and South America, and regions of Europe that border the Mediterranean.¹⁴⁰ Transmission of *Leishmania* spp is through the bites of sand flies, and three clinical syndromes are recognized: cutaneous, mucocutaneous, and visceral. Cutaneous and mucocutaneous forms may also be observed in the viscera in immunocompromised individuals. Visceral leishmaniasis caused by *Leishmania donovani*, *L. infantum*, and *L. i. chagasi* is characterized by fever, abdominal pain, and hepatosplenomegaly, often accompanied by anemia, thrombocytopenia, leukopenia, and generalized bone marrow suppression.

In immunocompromised patients such as those with HIV/AIDS,¹⁴¹ intracellular forms (amastigotes) may be observed in macrophages of many organs. In the respiratory tract, amastigotes have been observed in the mucosa of the larynx, and in the lung and pleura.¹⁴²⁻¹⁴⁷ Interstitial pneumonitis, granulomatous inflammation of the bronchial mucosa, and mediastinal lymphadenopathy have all been described in patients with visceral leishmaniasis.¹⁴⁸

Diagnosis and Treatment. Identification of the parasite by microscopy is the most commonly used method of diagnosis. Culture and molecular techniques such as PCR with *Leishmania* species-specific primers are also available. *Leishmania* amastigotes can be found in samples obtained by BAL, thoracentesis, or transbronchial biopsy.¹⁴⁹ Therapy of leishmaniasis includes pentavalent antimony compounds and amphotericin B formulations.¹⁴¹ More recently, miltefosine, an oral agent, has been approved for the treatment of *Leishmaniasis*.^{149a}

Microsporidiosis

Microsporidia are ubiquitous intracellular parasites found in invertebrate and vertebrate hosts and are believed to be related to fungi. The phylum contains more than 1200 species distributed into more than 192 genera; some have been associated with disease in humans. Microsporidia infect nearly all animal phyla, including other protists,

and they are important agricultural parasites in insects, fish, laboratory rodents, rabbits, fur-bearing animals, and primates. Microsporidia predominantly infect the digestive tract, but infections of almost all organ systems are documented.

Microsporidia that cause human disease are zoonotic and/or water-borne. *Enterocytozoon bienersi* and *E. intestinalis* are the most common human pathogens, followed by *E. cuniculi* and *E. hellem*. The emergence of the HIV/AIDS epidemic led to reports of these organisms associated with a diarrheal and chronic wasting syndrome. Risk factors include treatment with anti-TNF- α antibodies, chemotherapy, other immune-modulating drugs, and organ transplantation. Immune restoration by antiretroviral therapy has markedly reduced the incidence of microsporidiosis in HIV-infected people.¹²⁰

Clinical Features. Involvement of the respiratory tract and the sinuses by microsporidia may cause rhinitis, sinusitis, and nasal polyposis.^{150-155a} Involvement of the lower respiratory tract has been observed in the setting of disseminated disease and presents as an interstitial pneumonitis. *Enterocytozoon hellem* infection has been reported to involve the entire length of the respiratory tract, with manifestations including erosive tracheitis and bronchiolitis. There are case reports of *E. cuniculi*, *E. hellem*, and *E. intestinalis* causing bronchiolitis with and without pneumonia. Respiratory tract infection due to *E. bienersi* has also been reported.¹⁵⁶ *Tubulonosema acridophagus* infection with respiratory failure and pulmonary opacities has been described in which spores of the organism were recovered by BAL.¹⁵⁷

Diagnosis and Treatment. Diagnosis of microsporidia infection is made by finding parasite spores in clinical samples by microscopy; PCR-based molecular techniques are also available. Treatment depends on the species identified. In general, albendazole combined with immune reconstitution is the treatment of choice, although albendazole is not recommended for *E. bienersi* or *Vittaforma corneae* infection due to intrinsic resistance.¹²⁰

Trypanosomiasis

Trypanosoma cruzi is the cause of Chagas disease, which is found in areas of Mexico and in Central and South

America.¹⁵⁸ It is transmitted by Triatominae bugs or by blood transfusion, organ transplantation, ingestion of contaminated food and fluids, or vertical transmission (mother to child). Babies born with congenital Chagas disease have a variety of manifestations including pneumonia, and amastigotes have been reported in the lung in these cases.¹⁵⁹ Pneumonitis and acute pulmonary edema may be seen in acute Chagas disease. Congenital and acute disease are treated with either nifurtimox or benznidazole.¹⁶⁰

Patients with chronic Chagasic cardiomyopathy may have congestive heart failure and thromboembolic events. Chronic Chagasic patients with megaesophagus may have a variety of pulmonary complications including aspiration pneumonia, bronchiectasis, and lung abscess.

Key Points

- Helminthic parasites often migrate through the lungs en route to another organ, particularly the gastrointestinal tract. Migration is often associated with eosinophilia or eosinophilic pneumonia.
- Tropical pulmonary eosinophilia is in the differential diagnosis of eosinophilic pneumonias, and should be considered in any patient from an endemic area of filarial infections and who presents with eosinophilia and pulmonary opacities.
- Paragonimiasis, echinococcosis, and dirofilariasis can be symptomatic or asymptomatic, and present as pulmonary nodules or mass lesions.
- Pulmonary paragonimiasis is commonly associated with hemoptysis. Because tuberculosis and paragoni-

miasis often coexist in the same geographic areas of the world, it is important to examine the sputum and stools for ova and to perform a serologic test for this parasite in those suspected of tuberculosis.

- Schistosomiasis can cause pulmonary hypertension, usually after many years of untreated infection, which is thought to be due to deposition of eggs in pulmonary vessels, granuloma formation, and obstruction to blood flow.
- Strongyloidiasis is unique in that there is chronic infection with autoinfection that can result in a potentially lethal hyperinfection syndrome, particularly in patients given glucocorticoids.
- Protozoan parasites usually do not infect the lungs preferentially but, because many are highly prevalent in human populations, pulmonary disease may be seen, particularly as part of a disseminated infection.

eFIGURE IMAGE GALLERY

eFigure 39-1 Loeffler syndrome caused by ascariasis. A-D, Axial chest CT displayed in lung windows shows patchy bilateral nodular areas of ground-glass opacity. The patient complained of cough, hemoptysis, and chest pain, and was found to have peripheral eosinophilia. *Ascaris lumbricoides* infection was later diagnosed. (Courtesy Michael Gotway, MD.)

eFigure 39-2 Tropical eosinophilia. A, Frontal chest radiograph shows bilateral perihilar small nodules. The appearance is nonspecific and could be seen in a number of infections. *Wuchereria bancrofti* infection was confirmed. B, The patient was subsequently treated with diethylcarbamazine and doxycycline, leading to resolution of the small nodules. (Courtesy Michael Gotway, MD.)

eFigure 39-3 Paragonimiasis. Frontal chest radiograph in a patient with paragonimiasis shows patchy bilateral linear opacities and interstitial thickening associated with small nodules (*arrows*). (Courtesy Michael Gotway, MD.)

eFigure 39-4 Hydatid disease: *Echinococcus granulosus* infection. Frontal (**A**) and lateral (**B**) chest radiographs show a large homogeneous mass in the posterior right upper lobe. (Courtesy Michael Gotway, MD.)

eFigure 39-5 Hydatid disease: cystic *Echinococcal* embolization. A-D, Axial enhanced chest CT performed in a 23-year-old Arab woman shows multiple bilateral circumscribed nodules, some with a somewhat tubular shape (arrows, A). The soft tissue window images (C and D) show low attenuation embolic material, representing *Echinococcus* organisms, filling and expanding the pulmonary arteries (arrows, C and D). The source of the embolic material is the right atrium (arrows, C and D); note the faint internal septation within this mass. (Courtesy Michael Gotway, MD; case by Elaine M. Caoili, MD, University of Michigan, Ann Arbor, MI.)

eFigure 39-6 Amebiasis: colitis and liver abscess. **A**, Axial contrast-enhanced image through the liver (L) shows a low attenuation posterior right lobe liver abscess (*arrow*). **B**, Axial image through the pelvis shows thickening of the cecum (*arrowheads*), consistent with colitis. (Courtesy Michael Gotway, MD.)

IMPACT OF H1N1 INFLUENZA PANDEMIC OF 2009 ON BIOTERRORISM RESPONSE**RECOGNITION AND RESPONSE TO A BIOTERRORISM EVENT****INFECTION CONTROL****PUBLIC HEALTH AND CRITICAL CARE RESPONSE****INTRODUCTION**

Bioterrorism, once limited to military-directed biowarfare, has developed considerable prominence due to increasing world threats and the anthrax outbreak in the United States in 2001. Clinicians and public health officials have become more aware of these rare diseases as local, state, and national programs increase detection, therapeutic options, and responses to the causative agents.

Early recognition of bioterrorism agents can be difficult since the early prodromal phase of most agents is similar and often indistinguishable from other causes of febrile respiratory illnesses. Febrile respiratory illnesses and respiratory failure can signify a natural outbreak (e.g., severe acute respiratory syndrome, plague, tularemia, or a novel strain of influenza) or a bioterrorism event.^{1,2} Most cases of febrile respiratory illnesses admitted to *intensive care units* (ICUs) are caused by community-acquired pneumonia, and respiratory failure and *acute respiratory distress syndrome* (ARDS) subsequently develop in up to 11% of these community-acquired pneumonia cases.^{3,4} Although most cases of community-acquired pneumonia are recognizable, the rare and contagious causes (e.g., plague) can have a large impact on the health care and public health systems.^{2,5} Thus, early recognition of these infections becomes important for two reasons. First, early infection control and public health preparedness strategies must be implemented to reduce spread to health care workers and the public, particularly in the acute stages of disease when patients are most contagious and most likely to undergo aerosol-generating diagnostic procedures. Second, intentional release of these agents is a bioterrorism event, and public health and law enforcement authorities are now trained to provide immediate investigation and support. Therefore, early suspicion of a bioterrorism or outbreak event, along with early protective measures and public health contact, will reduce the likelihood of transmission to health care workers, visitors, patients, and the community.

Bioterrorism involves the deliberate release of viruses, bacteria, or their products (e.g., toxins) to cause morbidity and mortality in humans, animals, or plants.^{6,7} All bioterrorism agents are naturally occurring organisms or toxins that can cause sporadic disease under ordinary circumstances, but on occasion, an agent has been manipulated

to increase resistance to antibiotics or increase organism virulence.⁷ This chapter provides an overview of the major agents of bioterrorism and highly lethal disease outbreaks along with clues for detection, steps for public health response, and infection control interventions.

BIOTERRORISM: A HISTORICAL PERSPECTIVE

Bioterrorism has existed for centuries, from ancient Mesopotamia to current times.^{7,8} The initial goal was to incapacitate the enemy through death or stir panic in the population, leading to surrender. For example, in the 14th century, the Tartars catapulted plague-infected corpses into Kaffa, leading to disease spread and defeat of the city (also starting the second wave of the Black Death in Europe).⁹ In the New World, smallpox-contaminated blankets may have been distributed by early settlers to natives in an effort to overcome the siege of Fort Pitt. However, bioterrorism took form in the last 100 years with extensive biowarfare units in World War I and II.^{7,8} Notably, Unit 731 of the Japanese army in World War II used anthrax, plague, cholera, and typhoid on Chinese prisoners with high mortality, but the transition to the battlefield was less successful.⁷⁻⁹ The Cold War saw both the United States and the former Soviet Union develop bioweapon stockpiles that have since been dismantled. However, over the past 25 years, there has been an increase in individual-initiated bioterrorism, culminating in the anthrax outbreak in 2001 that used the postal service for distribution, causing 22 cases.^{7,8,10}

BASICS OF BIOTERRORISM

The route of transmission of bioterrorism agents can be by air (e.g., aerosol generation), food (e.g., botulism), or water (e.g., gastroenteritis agents). Delivery can mimic naturally occurring disease, especially if the food or water supply to the public has been targeted. However, with aerosol generation, rapid increases in new cases are seen in low-risk populations, as seen with the anthrax cases in 2001.¹¹

Because most bioterrorism agents are infectious diseases, presentation of disease is usually covert, with health care workers seeing the initial cases. Particularly with contagious diseases such as plague pneumonia, smallpox, and viral hemorrhagic fevers, secondary infections may propagate the event, allowing it to last weeks to months, stressing the capacity of the health care system.^{2,7} Chemical and explosive forms of terrorism, however, are often overt and immediately known, with first responders in the field evaluating the initial cases and subsequent cases rarely following the initial event. Therefore, epidemiologic evidence (e.g., an increase in pneumonia or a specific rash) may be the initial clue that there has been a bioterrorism event.¹²

The Centers for Disease Control and Prevention (CDC) has separated bioterrorism agents into three broad categories (A, B, and C) based on ease of spread and severity of illness.^{7,8,13,14} *Category A agents* are considered the highest risk to the public and national security for the following reasons: (1) easy person-to-person spread; (2) high mortality; (3) major public health impact causing panic and social disruption; (4) requirement for specific and specialized public health emergency response (e.g., public prophylaxis or protective equipment)^{7,8,13,14} (Table 40-1). *Category B agents* are moderately easy to spread and result in moderate morbidity but low mortality in those affected. Fewer specific public health responses are required (Table 40-2).⁷ *Category C agents* are considered future or potential threats because they are easily available and can have a high mortality, but they have not been documented or engineered successfully

Table 40-1 Centers for Disease Control and Prevention Category A Agents of Bioterrorism

Definition: Category A agents have the potential to be easily disseminated, have higher contagiousness, have high morbidity and mortality, and require increased public health preparedness

Anthrax (*Bacillus anthracis*)

Smallpox (variola major)

Plague (*Yersinia pestis*)

Tularemia (*Francisella tularensis*)

Botulism (*Clostridium botulinum* toxin)

Viral hemorrhagic fevers (filoviruses [e.g., Ebola, Marburg] and arenaviruses [e.g., Lassa, Machupo])

Table 40-2 Centers for Disease Control and Prevention Category B Agents of Bioterrorism

Definition: Category B agents are moderately easy to disseminate, carry a high morbidity but low mortality, and require public health laboratory and surveillance enhancements

PULMONARY AGENTS

Glanders (*Burkholderia mallei*)

Melioidosis (*Burkholderia pseudomallei*)

Psittacosis (*Chlamydia psittaci*)

Q fever (*Coxiella burnetii*)

Ricin toxin from *Ricinus communis* (castor beans)

NONPULMONARY AGENTS

Brucellosis (*Brucella* species)

Epsilon toxin of *Clostridium perfringens*

Food safety threats (e.g., *Salmonella* species, *Escherichia coli* O157: H7, *Shigella*)

Staphylococcal enterotoxin B

(Table 40-3).¹⁴ Although all of these agents can potentially cause serious disease, the category A agents, along with select category B agents, would be seen by clinicians and have the greatest impact on the public and health care system. These agents present initially with a nonspecific prodromal phase but with epidemiologic clues that may separate them from other less threatening causes of a febrile respiratory illness. Tables 40-4 to 40-8 list the unique features associated with category A agents: clinical syndromes, preferred diagnostic methods, radiologic features, treatment, and infection control and respiratory protection.

Table 40-3 Centers for Disease Control and Prevention Category C Agents of Bioterrorism

Definition: Category C agents have the future potential for engineering for easy dissemination or high mortality

Influenza (novel strain)

Nipah virus

Typhus disease (*Rickettsia prowazekii*)

Viral encephalitis (alphaviruses [e.g., Venezuelan equine encephalitis, eastern equine encephalitis, western equine encephalitis])

Water safety threats (e.g., *Vibrio cholerae*, *Cryptosporidium parvum*)

Table 40-4 Unique Clinical Syndromes Associated with the CDC Category A Agents of Bioterrorism

Agent	Unique Clinical Finding/Syndrome
Anthrax	Hemorrhagic mediastinitis
Smallpox	Poxlike rash with systemic inflammatory response syndrome leading to septic shock
Plague	Sudden acute respiratory failure and sepsis
Tularemia	Patchy alveolar pneumonia with sepsis
Botulism	Descending flaccid paralysis
Viral hemorrhagic fevers (e.g., Ebola)	Sepsis with bleeding diathesis, massive fluid loss from diarrhea and vomiting

Table 40-5 Preferred Diagnostic Methods for CDC Category A Agents

Agent	Laboratory Diagnostic Method
Anthrax	Culture of organism from blood or body fluid. Serology for uncultured cases. BSL 3 required at state and regional public health laboratory.
Smallpox*	PCR of pox lesion. EM confirmation, viral isolation from skin/fluid in BSL 4 laboratory (CDC only).
Plague	Culture of organism from blood or sputum. Serology for uncultured cases. BSL 3+ at state or regional public health laboratory.
Tularemia	PCR. Difficult to culture. Performed at local, state, and regional public health laboratories.
Botulism	Detection of toxin in blood or stool. Toxin identification (A-E) performed at state or regional public health laboratories.
Viral hemorrhagic fevers (e.g., Ebola)*	Nucleic acid detection by RT-PCR. Viral culture from blood/body fluid only performed under BSL 4 containment.

*Culture and/or species identification is performed at the CDC only.

BSL, biosafety level; CDC, Centers for Disease Control and Prevention;

EM, electron microscopy; RT-PCR, reverse transcription-polymerase chain reaction.

Table 40-6 Radiologic Features of CDC Category A Agents of Bioterrorism

Agent	Radiologic Pulmonary Findings
Anthrax	Widening of mediastinum (rapid enlargement on serial imaging), unilateral or bilateral hilar node enlargement. Peribronchovascular thickening and pleural effusion. May also have patchy alveolar opacities, but extensive consolidation uncommon. CT may show hyperattenuating lymphadenopathy
Smallpox	Patchy alveolar opacities
Plague	Patchy, potentially nodular bilateral opacities that may coalesce to more diffuse alveolar disease resembling ARDS. Cavitation uncommon. Lymph node enlargement possible, but inconsistent
Tularemia	Multifocal bronchopneumonia that may cavitate, or lobar pneumonia. Pleural effusion and lymphadenopathy not uncommon
Botulism	Normal to lower lung volumes
Viral hemorrhagic fevers (e.g., Ebola)	Few available data. Chest radiography may be normal. Diffuse alveolar opacities with areas of dense consolidation; widened mediastinum, pleural effusions also reported. American hantavirus-pulmonary edema pattern with interlobular septal thickening despite hypovolemia; may progress to bilateral air space opacities

Table 40-7 Treatment of Select CDC Category A Agents

Agent	Primary Treatment	Secondary Treatment
Anthrax	Ciprofloxacin 15 mg/kg IV twice daily Raxibacumab 40 mg/kg IV, one dose	Clindamycin 900 mg IV three times daily
Plague	Gentamicin 5 mg/kg IV/IM daily Streptomycin 1 g IM daily	Ciprofloxacin 15 mg/kg IV twice daily Chloramphenicol 15 mg/kg IV four times daily
Smallpox	Supportive care Vaccinia Immune Globulin (unproven in smallpox; approved for use in vaccine recipients with progressive vaccinia infection)	Cidofovir*
Tularemia	Gentamicin 5 mg/kg IV/IM daily Streptomycin 1 g IM daily	Doxycycline 100 mg IV twice daily Ciprofloxacin 15 mg/kg IV twice daily Chloramphenicol 15 mg/kg IV four times daily
Viral hemorrhagic fevers	Supportive care Ribavirin for Lassa fever	Investigational agents: Monoclonal antibodies, convalescent serum, antiviral agents
Botulism	Trivalent antitoxin (A, B, E) Supportive care	None

*Obtained through the CDC only (see <http://www.bt.cdc.gov/agent/smallpox/vaccination/vig.asp>).
CDC, Centers for Disease Control and Prevention; IM, intramuscularly; IV, intravenously.

Table 40-8 Infection Control and Respiratory Protection for CDC Category A Agents

Agent	Isolation	Baseline Protection	Protection in Higher Risk Procedures
Viral hemorrhagic fever	Contact	N95 mask with full face shield or PAPR; full skin coverage with fluid-resistant or impermeable gown or coveralls	Current CDC guidelines available at http://www.cdc.gov/vhf/ebola/hcp/procedures-for-ppe.html
Smallpox	Airborne and contact	N95 mask	N95 mask or PAPR
Botulism	None	None	Surgical
Plague*	Droplet and contact	N95 mask	N95 mask or PAPR
Tularemia	None	None	Surgical
Anthrax	None	None	Surgical

*Isolation can be stopped after 48 hours of appropriate antibacterial therapy.
PAPR, powered air-purifying respirator.

CDC CATEGORY A AGENTS

ANTHRAX

General

Anthrax is caused by *Bacillus anthracis*, a spore-forming gram-positive rod. *B. anthracis* is a normal soil inhabitant; the organism can multiply if soil conditions are favorable. Otherwise, *B. anthracis* persists for long periods in a spore form, resistant to decontamination and environmental

extremes. From the soil, *B. anthracis* spreads to herbivores, such as cattle, as they come into contact with spore-containing soil through grazing.^{15,16}

Human anthrax largely arises through contact with animal products, such as animal skins, where *B. anthracis* persists as spores. In 2001 in the United States, 22 cases of anthrax were due to an act of bioterrorism through the postal system, placing anthrax on the forefront of bioterrorism.¹⁰ Apart from this outbreak in 2001, anthrax remains rare in the United States, with most endemic and epizootic

Figure 40-1 Anthrax. The anthrax lesion on the skin of the forearm is caused by the bacterium *Bacillus anthracis*. The cutaneous ulceration has begun to turn black, hence the origin of the name “anthrax,” after the Greek word for coal. (Courtesy Centers for Disease Control and Prevention/#2033; James H. Steele.)

cases seen in the Middle East. Most cases in the United States arise through the handling of animal products, such as the 2006 cases associated with animal hide drum skins imported from Africa.¹⁶

Disease begins when *B. anthracis* spores are introduced subcutaneously or via ingestion or inhalation. After introduction to oxygen and a protein-rich environment, the spores convert to the vegetative (bacillus) form and initiate replication.^{15,16} Exotoxin secretion leads to local spread, edema, hemorrhage, and tissue necrosis. The anthrax capsule, edema factor toxin, and lethal factor toxin act in concert to drive disease.^{15,16}

Clinical Presentation

Three clinical disease syndromes are seen with anthrax: cutaneous, gastrointestinal, and inhalational.¹⁵⁻¹⁷ *Cutaneous anthrax* is the most common form worldwide and has an incubation period of 7 to 14 days after inoculation of spores into the subcutaneous space. This is followed by a small, painless papule that can be pruritic. The papule enlarges and develops a central vesicle, followed by erosion into a painless black eschar (Fig. 40-1). Marked edema (mediated by anthrax edema toxin) characteristically surrounds the lesions, and there may be regional lymphadenopathy, with systemic symptoms of fever and malaise. The hands, arms, face, and neck are the areas most commonly affected.

With *inhalational anthrax*, spores that reach the distal airways are transported by inflammatory monocytes or dendritic cells to the mediastinal lymph nodes, with replication followed by onset of disease.¹⁵ The incubation period averages 1 to 7 days, followed by clinical symptoms of a nonspecific febrile illness, often mimicking influenza. However, within 24 hours, disease rapidly progresses with the development of respiratory failure, hemorrhagic mediastinitis, necrotizing pneumonia, shock, multiorgan failure, and death (see Table 40-4).¹⁷ Shock and multiorgan failure can develop rapidly, and along with hemorrhagic mediastinitis (Fig. 40-2), are the clinical hallmark of anthrax.

Gastrointestinal anthrax is rare and is usually seen in family clusters following the consumption of undercooked meats of infected animals. The disease begins with development of bowel edema, followed by mesenteric lymphadeni-

tis and necrosis, and then rapid progression to shock and death.¹⁷

Mortality for cutaneous anthrax is low (<1% in treated patients; approximately 20% in untreated), while inhalational anthrax can carry a mortality of 89%.¹⁵⁻¹⁷ The inhalational cases from 2001 in the United States had a lower mortality of 45%.¹⁰

Diagnosis

Although the initial symptoms of inhalational anthrax are nonspecific, some early findings distinguish inhalational anthrax from influenza-like illness or community-acquired pneumonia. Compared with patients who presented with community-acquired pneumonia in a retrospective study, patients with inhalational anthrax were more likely to have nausea or vomiting, tachycardia, elevated transaminases, hyponatremia, and normal white blood cell counts.¹⁸ From these observations, a scoring system was devised that had approximately 80% sensitivity and 80% specificity for distinguishing inhalation anthrax cases.¹⁸

Diagnosis of anthrax is best performed by isolation of *B. anthracis* from cultures of blood, sputum, pleural fluid, cerebrospinal fluid, or skin^{16,19} (see Table 40-5). Clinicians should notify the laboratory of suspected anthrax, because spores can form during culture, leading to spread to laboratory workers if not properly handled. Additionally, any suspect case of anthrax should involve the public health laboratories for confirmation and strain typing. *Polymerase chain reaction* (PCR) and rapid *enzyme-linked immunosorbent assays* (ELISAs) are available and have good sensitivity and specificity.^{16,19}

The radiographic imaging findings associated with anthrax include a widened mediastinum consistent with hemorrhagic mediastinitis, the hallmark of inhalation anthrax^{15,16} (see Fig. 40-2) (see Table 40-6). However, during the 2001 outbreak, other findings, including patchy alveolar opacities, lobar consolidation, and pleural effusions, were also reported.¹⁶ In each of these cases, a widened mediastinum was present on chest radiograph, with follow-up confirmation performed by computed tomography scan.

Treatment, Prophylaxis, and Prognosis

Treatment includes supportive therapy and antibiotics^{17,19} (see Table 40-7). Intensive care management with early and appropriate volume resuscitation and lung-protective low tidal volume ventilation should be used if indicated.² Antibacterial treatment includes ciprofloxacin, doxycycline, or if the isolate is susceptible, penicillin.^{17,19,20} In 2001, rifampin, clindamycin, or vancomycin in combination with ciprofloxacin was used, because the isolate was resistant to penicillin.^{17,19,20} Pleural drainage or a central nervous ventriculoperitoneal shunt may also be used in individual cases. Corticosteroids are widely used to reduce edema and hemorrhage, especially when cutaneous anthrax affects the head and neck, threatening airway integrity, but there are very limited data on their efficacy.¹⁷

Raxibacumab, a human IgG1 monoclonal antibody directed against *B. anthracis* protective antigen (whose role is to bind host cells and deliver anthrax edema factor and lethal factor to the host cell cytoplasm), has been effective for the treatment of anthrax in animal models, with

Figure 40-2 Imaging findings in inhalation anthrax: chest radiography. **A**, Frontal chest radiograph in a 61-year-old man with a 3-day history of productive cough, fever, and exertional dyspnea shows poorly defined medial right upper lobe ground-glass opacity associated with a markedly widened right mediastinum (arrows). During recent travel through parks in the western United States, he had been exposed to animal antlers and hides, wild bison, and donkeys. **B**, Axial enhanced chest CT displayed in soft tissue windows shows right upper lobe consolidation (arrows) and a small right pleural effusion (*) and trace left pleural liquid associated with right paratracheal lymphadenopathy (arrowhead). *Bacillus anthracis* was isolated from blood culture. (Images courtesy Mark D. Sprenkle, MD, Pulmonary and Critical Care Medicine, Hennepin County Medical Center, Minneapolis, MN. Reprinted with permission from Sprenkle MD, Griffith J, Marinelli W, et. al: Lethal factor and anti-protective antigen IgG levels associated with inhalation anthrax, Minnesota, USA. *Emerg Infect Dis* 20:310–314, 2014.)

improved survival at 14 and 28 days.^{21,22} In 2012, raxibacumab was approved by the U.S. *Food and Drug Administration* (FDA) for the treatment of inhalation anthrax and, as such, should be used in combination with antibiotics and initiated when the diagnosis of inhalation anthrax is suspected or confirmed. An anthrax vaccine, prepared from the culture filtrate of an attenuated strain of *B. anthracis*, is approved for humans by the FDA, but its use has been limited, due to the need for multiple doses, local side effects, and efficacy concerns, and it is currently reserved for military personnel.²³ Exposure to aerosolized spores requires prophylaxis with either ciprofloxacin or doxycycline in adults; amoxicillin is a second-line agent in children and pregnant women.^{16,19} The recommended duration of post-exposure prophylaxis is 60 days, because none of the antibiotics eradicate spores, which may germinate weeks after exposure.

Infection Control

Anthrax is not transmitted from an infected person, because *B. anthracis* is in the vegetative form during clinical infection, and only spores are transmissible^{7,16} (see [Table 40-8](#)). Contact with infected animal carcasses and animal products (especially hides) can result in infection; wearing appropriate *personal protective equipment* (PPE) is indicated when handling these materials or when exposed to other suspected contaminated objects.

SMALLPOX

General

Variola virus is the causative agent of smallpox and is a member of the Poxviridae family.²⁴ Smallpox was eradicated worldwide in 1977, but now has regained interest because of its potential as a bioterrorism agent.^{24,25} Smallpox was widely endemic and at one point accounted for more than 10% of all deaths worldwide. Smallpox is very contagious; approximately half of all unvaccinated household contacts contract disease.^{24,25} After global eradication of smallpox was declared in 1977, routine vaccination for smallpox

ceased worldwide.²⁶ Due to an increasing unvaccinated population, along with its contagiousness and ability to be transmitted by aerosol, smallpox is a CDC category A bioterrorism agent. Only two stockpiles of the virus are known to remain (at the CDC and the Russian State Research Center).^{27,28}

Smallpox exists in two forms, variola major and variola minor.^{24,25} Variola major is the most common form of smallpox, has more severe disease with an extensive rash and fever, and carries a higher mortality (around 20% in the unvaccinated). Variola minor is less common and less severe, with mortality estimated at less than 1%. Variola minor has a genetic sequence very similar to that of variola major; quantitative differences in gene expression are thought to account for the variable mortality between the major and minor forms.

Clinical Presentation

Smallpox infection begins when the virus enters the respiratory tract, replicates locally, and is transported to regional lymph nodes.^{24,25} Viremia follows with spread to lymphoid organs, followed by further viral replication and progressive symptoms. Variola major presents in five major clinical categories: ordinary, modified, flat, hemorrhagic, and variola sine eruptione.^{24,25}

Ordinary type infection accounted for more than 70% of cases when smallpox was endemic. After an incubation period of 10 to 14 days, disease (pre-eruptive phase) manifests with high temperature, severe headache, and malaise. The pre-eruptive phase can last 2 to 4 days and is followed by the eruptive phase, which is characterized by rash. The lesions first appear as small erythematous macules on the mucous membranes, tongue, and face (herald spots).^{24,25,29} The lesions spread in a centrifugal fashion, with macules evolving into papules, then vesicles, and finally the classic pustules (pox) ([Fig. 40-3](#)) by day 5 to 7 of the rash (see [Table 40-4](#)). Fever usually resolves during the eruptive phase but may persist after the pustules develop. Crusting and healing begin by day 14 of the rash.

The *modified type* of variola major is similar to the ordinary type except that the rash is more rapid but less severe;

Figure 40-3 Smallpox. The maculopapular lesions on this patient's arm were caused by the smallpox virus, *variola major*. These lesions were in their pustular phase of development. (Courtesy Centers for Disease Control and Prevention/#10495; Dr. John Noble, Jr.)

this type was common in vaccinated individuals.^{24,25,29} The *flat type* had pustules that remained flat and confluent and often was seen in children.

The *hemorrhagic type* was rare but severe, with the lesions and mucous membranes becoming hemorrhagic.^{24,25,29} This type was more common in pregnant women and led to multiorgan failure within a few days.

The *variola sine eruptione type* is associated with fever but no rash; this type was often seen in previously vaccinated individuals.

Diagnosis

Diagnosis is largely clinical, with the acute onset of fever followed by the characteristic rash of deep-seated vesicles or pustules^{24,30} (see Table 40-5). For laboratory diagnosis, variola- and orthopox-specific PCR assays are performed at the CDC or World Health Organization–sponsored laboratories.^{24,30} If a case of smallpox is suspected, information on diagnosis, infection control, and public health measures are available at <http://emergency.cdc.gov/agent/smallpox/response-plan/index.asp>.

Radiographic imaging findings in smallpox are limited largely to diffuse alveolar opacities from an inflammatory response associated with the primary infection^{24,31} (see Table 40-6). Lobar opacities may be seen and are most often associated with secondary bacterial pneumonia.

Treatment, Prophylaxis, and Prognosis

Treatment is largely supportive, with some evidence that cidofovir, an antiviral with activity against cytomegalovirus, has activity in animal models^{24,31,32} (see Table 40-7). Aggressive ICU support, including volume resuscitation, vasopressor support, and low tidal volume ventilation should be used for severe cases.¹ Vaccination as soon as possible after exposure may reduce the severity of illness and is the mainstay for reducing spread and controlling disease in the community.²⁶ Vaccination administered within 4 days of exposure can still provide protection. Passive immunization with vaccinia immune globulin is FDA approved for patients suffering progressive vaccinia infection after vaccination; whether it has efficacy in treating smallpox has not been determined.

Mortality varies with the clinical category. The ordinary type carries a mortality from multiorgan failure and hypotension of around 20%, with the flat and hemorrhagic types carrying a higher mortality and the modified and sine eruptione types carrying a much lower mortality. Complications include secondary bacterial skin infections and pneumonia, along with encephalitis, orchitis, and extensive scarring of the skin and corneas.^{24,25}

Infection Control

Spread is through contact with infected lesions or respiratory secretions and thus full PPE, including respiratory protection, gown, gloves, and face shield, is required.³² CDC guidelines recommend airborne isolation with use of an N95 particulate respirator or a powered air-purifying respirator for respiratory protection, and all health care workers involved in care of a smallpox patient must be vaccinated against smallpox³² (see Table 40-8). If smallpox is suspected, public health officials must be contacted immediately.

PLAGUE

General

Yersinia pestis is the etiologic agent of plague and has caused multiple pandemics, despite being a recently evolved pathogen.⁹ Plague is a zoonosis, primarily affecting rodents; humans and other animals (especially domestic cats) are accidental hosts.^{33,34} The natural ecosystem of *Y. pestis* depends largely on the flea-rodent interaction, with seasonal variation based on environmental conditions that favor large rodent populations. Infected fleas bite their rodent hosts, inoculating the rodent. Mortality in these animals is lower than in nonrodent mammals, and disease is passed from infected rodent to flea and the life cycle continues. *Y. pestis* is transmitted to humans by bites from rodent-infected fleas, scratches or bites from infected animals, exposure to infected humans, or bioterrorism.^{33,34} Bites by infected fleas are the most common mode of transmission; squirrels, rabbits, domestic and wild cats, and prairie dogs are the most common sources of infected fleas. Large rodent or other animal die-offs, particularly in more susceptible species, may herald a large epidemic in nature.^{33,34} Plague is found worldwide; in the United States endemic disease is concentrated in the western states; most likely because of introduction of *Y. pestis*-infected rats through the ports of San Francisco, Los Angeles, and Seattle in the late 19th century.³⁵

Clinical Presentation

Three clinical syndromes are associated with plague: bubonic plague (80% to 90% of cases), septicemic plague (10% of cases), and pneumonic plague (very rare).^{33,34} After an incubation period of 2 to 7 days, symptoms usually arise, which differ depending on the clinical syndrome. The incubation period is prolonged and asymptomatic, due to multiple mechanisms used by *Y. pestis* to minimize early innate immune responses and inflammation, including specific inhibition of inflammasome activation.³⁶

In *bubonic plague*, a sudden onset of fevers, chills, and headache is followed by pain and swelling in the regional lymph nodes proximal to the site of the bite or scratch.^{33,34}

Figure 40-4 Plague. An axillary bubo and edema exhibited by a patient with plague. (Courtesy Centers for Disease Control and Prevention/#2061; Margaret Parsons, Dr. Karl F. Meyer.)

This lymph node (bubo) is characterized by intense tenderness with erythema and edema but without fluctuation (Fig. 40-4). Without treatment, disease disseminates, leading to pneumonia, meningitis, sepsis, and multiorgan failure. The development of secondary plague pneumonia is important to detect, because such patients are highly contagious.

In *septicemic plague*, acute fever is followed by sepsis without a bubo.^{33,34} Additional symptoms such as nausea, vomiting, and diarrhea also complicate septicemic plague. Sepsis, disseminated intravascular coagulation, and multiorgan failure develop quickly.

In *pneumonic plague*, most cases are secondary (hematogenous) from bubonic or septicemic plague, but primary pneumonic plague can also develop after exposure to infected humans, animals, or aerosols in an intentional bioterror attack.^{33,34} Initial cases in outbreaks of primary pneumonic plague have a very short incubation period of hours to a few days, followed by sudden onset of fever and cough, rapid onset of respiratory failure with ARDS, and death (see Table 40-4).

Diagnosis

The clinical diagnosis of plague can be difficult, but exposure to animals in an endemic area is an important clue to seek.^{33,34,37} (see Table 40-5). During intentional dissemination, multiple cases of severe, rapidly progressive pneumonia may be the first sign of an attack. Laboratory diagnosis is primarily by culture of the sputum or blood because *Y. pestis* grows well on routine laboratory media. Serology and rapid diagnostic testing by ELISA or PCR is also available but is used primarily in field testing.^{33,34,37}

On chest radiographs, a sudden and diffuse alveolar filling process is seen consistent with acute lung injury^{33,34} (see Table 40-6). Additional mediastinal lymphadenopathy may be present, as may pleural effusion in later stages. Lobar opacities are less common.

Treatment, Prophylaxis, and Prognosis

The primary agent for antibacterial therapy of plague has long been considered streptomycin but, based on its limited availability, gentamicin or doxycycline is preferred^{33,34} (see Table 40-7). Most isolates are susceptible to gentamicin and

doxycycline; most are also susceptible to ciprofloxacin, although there is less clinical experience with this drug in plague.³⁸ Chloramphenicol is preferred for cases of meningitis due to its ability to cross the blood-brain barrier. Because most cases of primary pneumonia lead to multiorgan failure and acute lung injury, volume resuscitation, vasopressor support, and low tidal volume ventilation are indicated.² There is no evidence of benefit from corticosteroids. Postexposure prophylaxis includes ciprofloxacin and doxycycline orally, with trimethoprim-sulfamethoxazole (if the isolate from the index case is susceptible) or gentamicin for children and pregnant individuals.³⁸

Infection Control

Due to the high rate of transmission of plague via aerosols, all patients should be on strict airborne isolation until at least 48 hours of antibiotics have been given³⁴ (see Table 40-8). Infection control measures include airborne isolation, including negative-pressure ventilation. Appropriate PPE, including an N95 mask or powered air-purifying respirator, should be worn by all personnel in contact with a patient with suspected or confirmed pneumonic plague.

TULAREMIA

General

Tularemia is caused by the gram-negative bacterium *Francisella tularensis* and is a zoonotic disease; humans are accidental hosts.³⁹ *F. tularensis* is found throughout the Northern Hemisphere in a wide variety of wild and domesticated species and the organism persists in nature. Humans become infected by the bites from infected vectors (ticks and flies), the handling of infected animals, ingestion of improperly prepared animal meat, animal scratches and bites, the drinking of contaminated water, or inhalation of an aerosol of the organism from the environment or in a bioterrorism event.³⁹⁻⁴¹ Human-to-human transmission has not been described.

Clinical Presentation

Six distinct clinical syndromes have been observed with tularemia: ulceroglandular, glandular, typhoidal, pneumonic, oropharyngeal, and oculoglandular.^{42,43} *Ulceroglandular disease* accounts for approximately 60% to 70% of cases.^{42,43} After an incubation period of 2 to 10 days, there is an abrupt onset of fevers, chills, headache, and malaise. Most patients have a single papuloulcerative lesion with a central eschar and associated tender lymphadenopathy (Fig. 40-5). In *glandular disease*, lymph nodes enlarge without the characteristic lesion (about 15% of cases).^{42,43}

Pneumonic tularemia results from primary inhalation or hematogenous spread from typhoidal tularemia, and this is expected to be the main clinical presentation in a bioterrorism event with tularemia.⁴⁰ The incubation period tends to be shorter in these cases, with the rapid onset of pneumonia. Respiratory failure and ARDS develop rapidly (see Table 40-4).

Typhoidal tularemia is rare and is seen with or without pneumonia; patients present with a febrile illness followed by sepsis without the glandular disease.⁴³ *Oropharyngeal tularemia* results when undercooked infected meat or water

Figure 40-5 Tularemia. A tularemia lesion is shown on the dorsal skin of the right hand caused by the bacterium *Francisella tularensis*. (Courtesy Centers for Disease Control and Prevention/#2032; Dr. Brachman.)

is ingested and is associated with fever, pharyngitis, and cervical lymphadenopathy.⁴³

Oculoglandular tularemia results from direct inoculation from contaminated fingers or accidental exposure. Conjunctival swelling and erythema, and regional lymphadenopathy may be present.

Diagnosis

Culturing *F. tularensis* is suboptimal in a few respects: specific culture media (with cysteine) is required, growth is slow, and cultures are hazardous to laboratory personnel^{44,45} (see Table 40-5 and Chapter 17, Table 17-5). PCR detection of *F. tularensis* is rapid, is not hazardous, and has a reported sensitivity of approximately 75% and high specificity (see Table 17-5). PCR-positive fresh samples should be submitted to a reference or public health laboratory for confirmation.

Radiographic imaging studies show patchy opacities bilaterally, lobar disease, and hilar adenopathy⁴⁶ (see Table 40-6). There can also be pleural effusions and a miliary pattern, and hilar and mediastinal adenopathy.

Treatment, Prophylaxis, and Prognosis

Similar to the treatment for plague, gentamicin is the treatment of choice for tularemia^{45,47} (see Table 40-7); doxycycline or ciprofloxacin may be used as second-line therapy. For meningitis, chloramphenicol is preferred. Postexposure prophylaxis with doxycycline or ciprofloxacin may be efficacious, with trimethoprim-sulfamethoxazole or amoxicillin for children and pregnant patients.^{45,47} ICU management of tularemia includes supportive care and low tidal volume ventilation for ARDS. The overall mortality for tularemia is around 4%, but is thought to be higher in aerosolized disease that causes pneumonia or typhoidal tularemia.^{42,43}

Infection Control

Tularemia is not spread by human-to-human contact, so once the diagnosis is confirmed, respiratory isolation can be discontinued^{43,47} (see Table 40-8). Rules about reporting tularemia to public health officials varies across North America but pneumonic or typhoidal cases, particularly if thought to be secondary to a bioterrorism event, must be reported.

BOTULISM

General

Clostridium botulinum, a gram-positive, spore-forming, obligate anaerobe, is the bacterium that produces and excretes botulinum toxin.^{48,49} This neurotoxin is responsible for the clinical disease known as botulism and is the only category A agent that is a toxin. Seven serotypes of botulinum toxin exist, A through G, and are produced by different strains of *C. botulinum*. All botulinum neurotoxins act as proteases that cleave proteins on synaptic vesicles or the presynaptic plasma membrane of the neuromuscular junction and cholinergic autonomic synapses. The resulting inability to release neurotransmitters and disruption of neurotransmission account for the clinical findings. Serotypes A, B, and E predominate in human disease, although any serotype can cause disease.^{48,49} Serotypes C and D are predominantly found in animal populations. Botulinum toxin is extremely potent, with the median lethal oral dose estimated to be 1 ng/kg, although the lethal dose may be two to three times higher if exposure is by inhalation.^{48,49}

Disease presents from four potential sources: food-borne, wound, infant, and intentional.^{48,49} Food-borne disease presents in outbreaks and is often associated with home-canned foods, such as fruits, vegetables, and fermented fish. Wound botulism has been associated with intravenous and subcutaneous injection of black tar heroin, mostly of Mexican origin. Infant botulism is seen sporadically in some western states, likely from spore acquisition from soil or raw honey, with toxin production in the gastrointestinal tract. Finally, intentional release during a bioterrorism event may lead to oral ingestion or inhalation of the toxin.

Clinical Presentation

Botulism begins with the acute onset of bilateral cranial neuropathies with rapidly descending weakness (see Table 40-4). No fever is present and mental status is not affected.^{48,49} The cranial neuropathies are usually symmetrical and often begin with oculomotor dysfunction. However, asymmetrical cranial nerve dysfunction has been reported.⁵⁰ Diplopia, dysphagia, ptosis, and facial weakness are the most common early complaints.^{48,49} In food-borne exposure, there may also be gastrointestinal symptoms, including nausea and vomiting. In infant botulism, poor feeding and lethargy may be the only symptoms. Food-borne botulism usually has an onset of symptoms 12 to 36 hours after exposure; symptoms rapidly progress over the next 12 hours. If botulism is not suspected and treatment is not started rapidly, weakness and paralysis of respiratory muscles ensues, requiring mechanical ventilatory support.⁵⁰ Once the muscles of respiration are involved, mechanical support may be required from 1 to 3 months.⁵⁰ Since the toxin-mediated blockade of neuromuscular transmission is reversible, full recovery can be expected although recovery may be prolonged.

Diagnosis

Early and prompt diagnosis is essential because respiratory support is often required and early treatment may alter the extent of progression of weakness. Thus the clinical findings of cranial nerve palsies, particularly in the appropriate clinical setting (e.g., heroin use, or ingestion of the same

food as another person with botulism) should prompt consideration of botulism (see Table 40-5). Laboratory diagnosis is by toxin detection or organism isolation.⁴⁵ Detection of toxin in blood or stool is most reliable.⁵¹ The growth of *C. botulinum* from a stool or wound sample with the corresponding clinical findings can also confirm the diagnosis. Electromyography will also support the diagnosis if toxin and organism isolation is unsuccessful. There are no specific radiologic changes seen with botulism. Low lung volumes on chest radiographs may be seen but are not specific (see Table 40-6).

Treatment, Prophylaxis, and Prognosis

Supportive care is the cornerstone of management of botulism. Monitoring for impending respiratory failure and providing mechanical ventilation when needed are the highest priorities. An equine trivalent antitoxin (against serotypes A, B, and E) is available from state public health departments and the CDC, and is directed at neutralization of toxin that has not yet entered cells. Botulinum antitoxin cannot reverse botulinum intoxication^{48,49,52} (see Table 40-7). While the antitoxin is widely used in cases of botulism, its efficacy has only been inferred and, since the available antitoxin is derived from immunized horses, anaphylaxis and/or serum sickness can develop in 9% to 20% of recipients. A human-derived antitoxin is available but only for infant botulism. Human monoclonal antibodies have been prepared that neutralize multiple types of botulinum toxins, and these provide the potential for use in adults with a lower risk of adverse effects than the equine antiserum.⁵³ In wound botulism, after wound drainage, antibiotic administration is useful; penicillin or clindamycin are the drugs of choice.^{48,49} In food-borne and inhalation botulism, because the disease results from exposure to the toxin and not from infection, antibiotics are not efficacious. In all cases of botulism, routine monitoring of forced vital capacity is recommended, with early intubation if the vital capacity falls below 10 mL/kg (approximately 30% predicted). There is no direct prophylaxis for exposure, but in the setting of high-risk threats, a vaccine directed against serotypes A and E is available and has been largely used in the military.⁵² Patients die of botulism due to respiratory failure without ventilatory support or from complications during critical care.

Infection Control

Because botulism is a toxin-based disease, no specific infection control measures are required⁴⁸ (see Table 40-8). An exposure to spores or toxin should be followed by decontamination, although secondary infections or intoxication in medical personnel have not been reported.

VIRAL HEMORRHAGIC FEVERS

General

The hemorrhagic fever viruses include multiple geographically distributed viruses, including Ebola and Marburg viruses, and the viruses causing Rift Valley fever, Bolivian, Argentine, and Crimean-Congo hemorrhagic fevers, Lassa fever, yellow fever, and dengue fever.⁵⁴⁻⁵⁶ Ebola and Marburg viruses are in the family Filoviridae; Lassa virus and the

viruses causing Bolivian (Machupo virus) and Argentine (Junin virus) hemorrhagic fever are in the family Arenaviridae. The Crimean-Congo and Rift Valley fever viruses belong to the Bunyaviridae family. Only the Filoviridae (Ebola and Marburg viruses) and Arenaviridae are listed as category A agents. The Filoviridae family serves as a classic template for viral hemorrhagic fevers and is largely discussed here.⁵⁴ Marburg virus has a single species, while Ebola virus has five different species that vary in virulence in humans.^{55,56} Transmission appears to be through contact with blood or secretions of nonhuman primates and infected individuals. People have become infected after handling primate products, after consuming nonhuman primate meat, or after exposure to symptomatic patients, including in hospitals. Several cases have presented due to exposure in laboratories. The use of hemorrhagic fever viruses as bioterrorism agents has also been postulated, largely based on their high contagiousness in aerosolized primate models.^{55,56} The animal reservoir for these viruses was initially thought to be wild primates, but has recently been tentatively identified to be bats, which transmit the infection to nonhuman primates in the wild.

Clinical Presentation

The clinical manifestations of both Marburg and Ebola viruses are similar in presentation and pathophysiology.^{56,57} The incubation period after exposure to either virus is usually 5 to 10 days, but may be as long as 19 days. Clinical disease begins with the abrupt onset of fever, chills, malaise, severe headache, nausea, vomiting, diarrhea, and abdominal pain.^{56,57} Over the next few days, symptoms worsen to include prostration, stupor, and hypotension. In some patients, coagulation becomes impaired with the appearance of increased conjunctival and soft tissue bleeding. In some of the reported outbreaks, hemorrhage can be massive in the gastrointestinal and urinary tracts and, in rare instances, the lung.^{56,57} In the outbreak of Ebola virus disease centered in Guinea, Liberia, and Sierra Leone in 2014, hemorrhage was not prominent; instead, the clinical picture was dominated by voluminous diarrhea.^{57a,57b} The onset of maculopapular rash on the arms and trunk may be a very distinctive sign (Fig. 40-6). Along with volume depletion and hypotension, multiorgan failure can develop and often leads to death (see Table 40-4). Outbreaks and cases have largely been described in developing countries where critical care resources are limited, thus experience with mechanical ventilation and the development of ARDS is not well documented. Case-fatality rates have ranged from 40% to 90%.^{54,56,57,57b,58}

Diagnosis

It is important to suspect the diagnosis of a viral hemorrhagic fever in order to initiate supportive care before the onset of shock, to involve the public health department, and to implement infection control measures. Viral hemorrhagic fevers should be suspected in cases of an exposed laboratory worker or an acutely ill traveler from an endemic area (i.e., central or west Africa), or in the presence of characteristic clinical findings in the context of other cases in the community, suggesting a bioterrorism attack.⁵⁶ The presence of high temperature, malaise and joint pain, conjunctival bleeding and bruising, vomiting and diarrhea,

Figure 40-6 Marburg virus. This posterior-oblique view of the back of a patient shows the measles-like maculopapular rash, which can appear on patients with the Marburg virus infection around the fifth day after the onset of symptoms, and usually may be found on the patient's chest, back, and stomach. This patient's skin blanched under pressure, which is a common characteristic of a Marburg virus rash. (Courtesy Centers for Disease Control and Prevention/#6571; Dr. J. Lyle Conrad.)

confusion, and progression to shock and multiorgan failure should raise suspicion of a viral hemorrhagic fever. Laboratory diagnosis consists of viral nucleic acid detection by PCR⁵⁶ (see Table 40-5).

Radiologic changes include a diffuse alveolar process consistent with acute lung injury^{56,57} (see Table 40-6). As the disease progresses, the alveolar process can become dense as alveolar hemorrhage develops. Pleural effusions may also be present.

Treatment, Prophylaxis, and Prognosis

Current patient management includes supportive care, including aggressive volume resuscitation, and a lung-protective strategy with low tidal volume ventilation if ARDS is part of the disease course⁵⁵⁻⁵⁷ (see Table 40-7). Recent experiments in nonhuman primates have established therapeutic efficacy of a combination of three monoclonal antibodies to the Ebola glycoprotein.⁵⁹ This provides proof of principle that specific treatment of Ebola infection is possible, and the humanized monoclonal antibodies may progress to availability for human use. With the arenavirus group (Lassa, Junin, and Machupo viruses) and the Bunyaviridae (Crimean-Congo hemorrhagic fever and Rift Valley fever viruses), ribavirin is recommended.⁵⁵⁻⁵⁷ The recent finding that Ebola replication requires the *Abelson tyrosine kinase* (C-abl), and that C-abl kinase inhibitors (currently used for treatment of chronic myelogenous leukemia and certain other malignancies) block Ebola replication in vitro suggests an additional potential treatment approach.⁶⁰

If a health care worker is exposed, there is no approved postexposure prophylaxis; infection control and occupational health personnel should be involved immediately. Two distinct vaccines protect nonhuman primates against Ebola challenge and are entering initial trials in humans.^{61,62}

Infection Control

Transmission is by the droplet route, and the very high viral loads found in blood, diarrhea, and secretions in Ebola

patients mandate stringent precautions to protect personnel. Placement of the patient in an isolation room with strict procedures for handling waste is essential to protect healthcare and other personnel⁵⁵⁻⁵⁷ (see Table 40-8). Equipment should be dedicated to that individual, and all higher risk procedures must be done with full PPE. Any suspected case of viral hemorrhagic fever should immediately involve the public health officials and infection control department, because public health interventions and outbreak investigation are essential to reduce spread of disease within the community and to investigate any potential bioterrorism attack.

SELECT CDC CATEGORY B AGENTS

DIRECT PULMONARY AGENTS

Glanders (*Burkholderia mallei*)

Glanders is caused by the gram-negative bacterium *Burkholderia mallei*.⁶³ It is primarily a disease of horses; humans become infected through broken skin or droplet inhalation. Naturally occurring human infection is rare, but occupational cases (principally in horse veterinarians) are seen sporadically. In bioterrorism, aerosolization is the anticipated method of exposure. Glanders can present as an acute or chronic skin infection, but with aerosolization, rapid pneumonia and/or sepsis can result.⁶³ Diagnosis is by culture, but *B. mallei* can be misclassified by some automated systems as a *Pseudomonas* species. Treatment includes supportive care as well as systemic antibiotics such as a third-generation cephalosporin, imipenem, or ciprofloxacin.⁶³ Human-to-human transmission has not been detected, but universal precautions with droplet isolation for respiratory cases are recommended. Any suspect case should prompt immediate notification of the public health department.

Melioidosis (*Burkholderia pseudomallei*)

Melioidosis is caused by the gram-negative bacterium *Burkholderia pseudomallei*.^{63,64} Unlike *B. mallei*, this bacterium has a natural reservoir in the soil and contaminated water and is spread through direct contact or inhalation. Thus disease predominates during the rainy season. In bioterrorism, aerosolization would lead to a clinical picture of pneumonia or melioidosis sepsis.^{63,64} With melioidosis, the incubation period can be highly variable, with some cases presenting acutely, some having extended incubation periods, and others remaining asymptomatic.⁶³⁻⁶⁵ Sepsis with multiple metastatic foci develops in most symptomatic cases, eventually progressing to multiorgan failure. Diagnosis is by culture using routine methods. Treatment involves imipenem or a third-generation cephalosporin, followed by a 20-week treatment with doxycycline and trimethoprim-sulfamethoxazole for eradication of metastatic foci.^{63,64}

Psittacosis (*Chlamydia psittaci*)

Psittacosis is caused by *Chlamydia psittaci*, an intracellular bacterium routinely associated with birds such as parrots, cockatiels, and canaries. Psittacosis presents

nonspecifically, and most cases go undiagnosed.^{66,67} As a category B bioterrorism agent, *C. psittaci* can cause morbidity with low mortality. Intentional aerosolization would lead to multiple cases of nonspecific “atypical pneumonia” with cough, fever, and headache.^{66,67} Diagnosis has historically been difficult, but sensitive PCR techniques offer the potential for rapid, specific diagnosis (see Chapter 17; Table 17-1). Treatment is with doxycycline, a macrolide, or ciprofloxacin. Mortality is low at 1% in treated cases.^{66,67} Universal precautions are required for patient care, although an N95 mask and coveralls are recommended for environmental decontamination.

Q Fever (*Coxiella burnetii*)

Q fever is a zoonotic disease caused by *Coxiella burnetii*. Cattle, sheep, and goats are the primary reservoirs of *C. burnetii*; this disease is found worldwide.⁶⁸ *Coxiella burnetii* usually does not cause clinical disease in animals, but organisms are found in milk, urine, feces, amniotic fluids, and placenta. The organisms are resistant to heat and drying, and can cause infection by inhalation of environmental dust contaminated with dried placental material, birth fluids, and excrement. The incubation time is 1 to 2 weeks, after which clinical illness develops in approximately 50% of infected persons.⁶⁸ Q fever is characterized by high temperatures (often greater than 40°C/104°F), severe headache, myalgia, sore throat, nonproductive cough, nausea, vomiting, diarrhea, abdominal pain, and chest pain.^{68,69} Pneumonia develops in 30% to 50% of patients with symptomatic infection.

One percent to 2% of people with acute Q fever die of the disease.^{68,69} In a small percentage of those infected, chronic Q fever (infection that persists for more than 6 months), including endocarditis, develops; up to 65% of persons with chronic Q fever die of the disease. Diagnosis of Q fever depends on serologic testing, most commonly using the indirect immunofluorescence assay (see Chapter 17; Table 17-5).^{68,69} The antibiotic treatment of choice for acute Q fever is doxycycline 100 mg twice daily for 15 to 21 days.^{68,69} Fluoroquinolones may be effective alternatives.

Ricin Toxin

Ricin is a potent biologic toxin (toxic protein) derived from castor beans (*Ricinus communis*) during manufacture of castor oil.⁷⁰ Ricin acts as a toxin by the inhibition of protein synthesis; 0.2 mg (1/5000th of a gram) is thought to be the lethal dose. Symptoms begin within 4 to 12 hours after exposure. Systemic effects of ricin poisoning depend on route of exposure and exposure dosage. Signs and symptoms from oral ingestions include vomiting and profuse diarrhea; in addition, there may be fever, myalgia and arthralgia, hallucinations, and seizures.⁷⁰ Hypovolemic shock and multiorgan failure may intervene, and represent the likely cause of death.⁷⁰ Based on animal experiments, after an inhalational exposure, symptoms in humans are expected to include cough, respiratory distress, and bronchoconstriction. Influenza-like symptoms (fever, myalgia, and arthralgia) may be seen, as can hypotension, respiratory failure, and multiorgan failure.⁷⁰ Few symptoms and signs exist to separate ricin intoxication from other causes of respiratory failure, although excessive diaphoresis has been reported and would be unusual in other causes. No

specific treatment or antitoxin exists. Treatment consists of decontamination and supportive therapy.⁷⁰

NONPULMONARY AGENTS (GASTROINTESTINAL AND TOXIN)

Brucellosis (*Brucella* Species)

Brucellosis is caused by a number of species within the genus *Brucella*. Disease is common in livestock workers, particularly in areas of poor sanitation, where *Brucella* is found in domesticated animals.⁷¹ *Brucella* is a category B agent due to its low mortality and prolonged incubation period.⁷² After exposure through ingestion of contaminated food or intentional aerosolization, symptoms develop after a few weeks to months. Initially fevers persist irregularly over weeks to months, followed by arthralgias, gastrointestinal symptoms, and possibly endocarditis.⁷¹ Diagnosis is suspected with a plausible history of exposure, with isolation of the organism by blood culture. However, growth is slow, so all cultures should be kept for 4 weeks if the diagnosis is suspected. Treatment is with doxycycline for up to 6 weeks, for children, treatment is with trimethoprim-sulfamethoxazole for children.⁷¹

Epsilon Toxin of *Clostridium perfringens*

The *Clostridium* species produce multiple toxins; epsilon toxin is produced by *Clostridium perfringens* types B and D.⁷³ The toxin acts on host cell membranes, producing pores that cause nonselective permeability. *Clostridium perfringens* uses the toxin to gain access into the bloodstream from the gut. However, in bioterrorism, intentional release via ingestion or inhalation of the toxin alone is most likely.⁷⁴ Based on data from animals, rapid ingestion or inhalation would cause diffuse tissue edema and be manifested as central nervous system dysfunction (weakness, ataxia, confusion), pulmonary edema (shortness of breath, cough, bronchospasm, respiratory failure), nausea, vomiting, tachycardia, and hypotension.⁷³ Diagnosis requires clinical suspicion consistent with a bioterrorism attack; the toxin can be detected by ELISA. Treatment is supportive, with penicillin if *C. perfringens* is present in addition to the toxin.⁷³

Food Safety Threats (e.g., *Salmonella* Species, *Escherichia coli* O157:H7, *Shigella*)

Enteropathogenic gram-negative bacteria, such as *Escherichia coli*, *Salmonella*, and *Shigella*, constitute a large group of agents that make up food supply threats.⁷⁵ Public health officials are familiar with these bacteria from numerous episodes of food contamination that lead to localized outbreaks and large product recalls. In an intentional release, these agents would produce widespread gastrointestinal symptoms leading to significant morbidity but with low mortality. After an incubation period of 3 to 7 days, there would be abdominal cramping, nausea, vomiting, and diarrhea. The diarrhea may be voluminous and bloody.⁷⁵ Diagnosis is by stool culture of the agents. An aggressive public health investigation usually yields the initial agent, because bioterrorism resembles a point-source outbreak.⁷⁶ Treatment is intravenous hydration as needed and, with some agents (*Salmonella*, *Shigella*), antibacterial therapy with ciprofloxacin.⁷⁶

Staphylococcal Enterotoxin B

Staphylococcal enterotoxin B is a toxin produced by *Staphylococcus aureus* commonly associated with food poisoning. Symptoms of food poisoning include vomiting and diarrhea several hours after ingesting food.⁷⁷ Naturally occurring, it is rarely lethal. The clinical presentation would depend on the route of administration. Oral administration (poisoning of food or water supplies) would present as vomiting and diarrhea.⁷⁷ If inhaled, respiratory failure with neurotoxic effects may be seen.⁷⁷

IMPACT OF H1N1 INFLUENZA PANDEMIC OF 2009 ON BIOTERRORISM RESPONSE

In 2009–2010, a new variant of H1N1 influenza A virus emerged and caused a global influenza pandemic.⁷⁸ Treatment strategies and interventions used in this H1N1 pandemic have impacted the planning for responses to highly infectious agents, including agents of potential bioterrorism. The administration of antivirals, particularly oseltamivir, reduced hospitalizations and death when administered within 48 hours of symptom onset.^{79–82} In critically ill patients with pandemic H1N1 influenza, oseltamivir was associated with increased survival compared with no treatment (75% versus 58%) with a median time of treatment initiation 4 days from symptom onset.⁷⁹ However, treatment initiated within 5 days after symptom onset was still associated with increased survival compared with no therapy.^{80,81} Similar findings were seen in children and other at-risk individuals, including immunocompromised and pregnant women.⁸² Therefore the importance of early distribution and administration of therapy, including the rapid dissemination of therapy guidelines for practitioners, must be a cornerstone of any bioterrorism response.

Additional adjunctive therapies during the H1N1 pandemic also became a cornerstone of response, including the use of extracorporeal membrane oxygenation, which was used in some patients with ARDS (predominately single organ failure) resulting from pandemic H1N1 influenza. Small observational studies suggested a mortality benefit in patients who received extracorporeal membrane oxygenation.^{83,84} However, extracorporeal membrane oxygenation is only performed at specialized centers and is resource intensive, thus requiring regional and statewide coordination in order to ensure success. Additional therapies, such as corticosteroids, inhaled nitric oxide, N-acetyl cysteine, and proning were also administered without established benefit.⁸⁵

RECOGNITION AND RESPONSE TO A BIOTERRORISM EVENT

The recognition of a case of a disease related to a bioterrorism event relies on a high index of suspicion by the clinician. However, recognition may be difficult in the early stages of disease, in that many of the category A agents

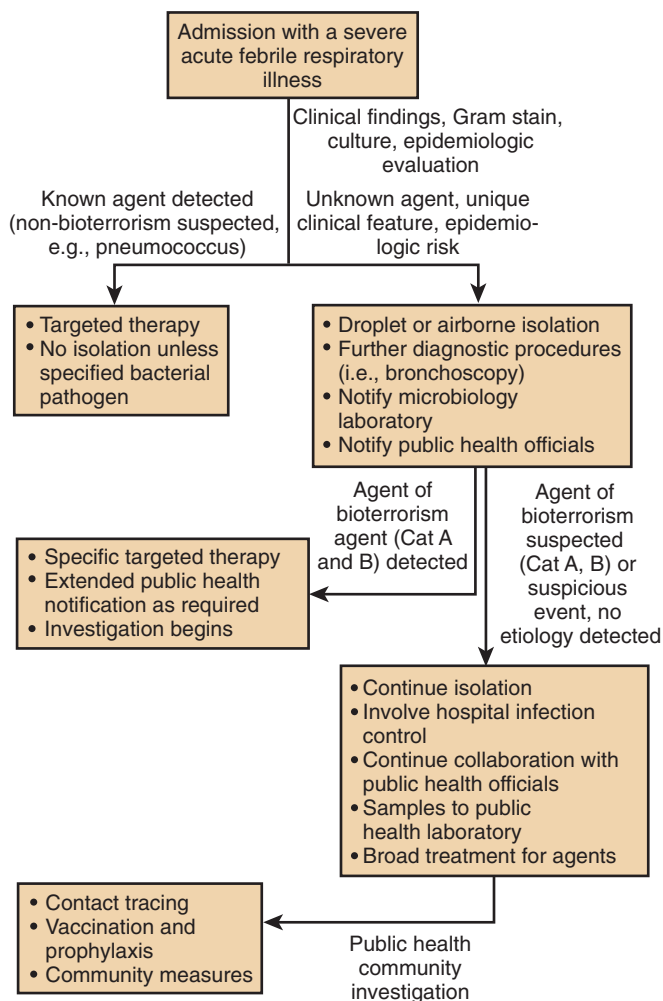

Figure 40-7 Schema of response to acute febrile illness with respiratory failure. A coordinated response to an acute febrile illness with respiratory failure is outlined involving diagnosis and treatment, respiratory precautions for hospital staff, and involvement of hospital infection control and public health officials.

present with nonspecific symptoms.⁸⁶ Figure 40-7 outlines an approach to early isolation, testing, and involvement of institutional infection control and public health officials in cases of acute febrile illness. Upon admission, cases of acute febrile illness and respiratory failure should undergo initial diagnostic testing, including pretreatment Gram stain, respiratory culture, and urine antigen testing for *Legionella*. If an etiologic agent is identified on initial screening and clinical findings (i.e., gram-positive diplococci with a lobar pneumonia on radiograph), targeted treatment should be initiated, with appropriate isolation precautions based on the pathogen. However, if an agent is not easily identified, patients should be placed in isolation and further diagnostic testing should be performed. If multiple cases with similar symptoms or a case with an uncommon epidemiologic link is determined, patients should be isolated and public health officials should be contacted. If specific clinical features subsequently arise, then directed diagnostic testing should be performed. If no clear etiology is detected, further evaluation is warranted with invasive and expanded testing.

Although bronchoscopy generates aerosols that increase the risk of transmission, bronchoscopy should be performed with appropriate protection of personnel in these cases, because identification of the etiology of illness is an essential component of an appropriate public health response. The public health authorities and the institutional infection control should be contacted as early as possible when clinical suspicion of bioterrorism arises or when diagnostic tests do not yield results.

Once a bioterrorism agent is suspected, the diagnosis is confirmed by specialized public health laboratories. Initial cases must meet a case definition for the suspected agent (see <http://emergency.cdc.gov/bioterrorism/casedef.asp>) before there is further evaluation. In order to meet the case definition, at least one critical distinguishing feature must be met along with other clinical and laboratory features.

INFECTION CONTROL

Involvement of institutional infection control, microbiology, and public health experts must be initiated as early as possible. They should be notified when there is one of four conditions: (1) a clinical or epidemiologic feature suggestive of bioterrorism (see Table 40-4), (2) an unexpected clinical link or increase in number of cases (e.g., pneumonia with respiratory failure), (3) an extensive workup of a febrile respiratory illness fails to reveal an organism and an infectious disease is suspected, or (4) transmission of disease to health care workers. Hospital infection control will assist in isolation and health care worker protection, and the hospital microbiology laboratory should be notified of suspected pathogens, allowing for worker protection and targeted testing of samples.^{1,87} Finally, public health involvement allows a broader diagnostic testing, including subtyping and resistance testing. If the agent is a novel or emerging pathogen, as seen with severe acute respiratory syndrome or avian influenza, early public health involvement allows for rapid laboratory testing, epidemiologic investigation, case definition, and community prevention.

The basic infection control requirements are outlined in Table 40-8. Anthrax and botulism are the only category A agents that are not contagious and do not require respiratory protection for caregivers. If the number of cases exceeds the health care capacity for isolation, patient cohorting and accessory isolation measures can be used. Finally, higher risk procedures should be limited in these cases (Table 40-9). Aerosol-generating procedures are most common in ICU patients, and reducing unnecessary risky procedures reduces patient and health care worker risk. However, these procedures should be performed if needed. Appropriate PPE should be worn by health care workers at all times and, if worn properly, reduces the risk of disease transmission.⁸⁸

PUBLIC HEALTH AND CRITICAL CARE RESPONSE

Acts of conventional terrorism, such as with explosive devices or chemical attacks, result in a single point of mass

Table 40-9 Respiratory Care Procedures That Carry a Higher Risk for Disease Transmission in Patients with a CDC Category A Agent

Nebulization of medication

Bronchoscopy
Humidified oxygen delivery
Non-rebreather mask without expiratory filter

casualties with an immediate critical area response. In contrast, because some of the category A agents are spread by contact and respiratory transmission, new cases will be seen after the initial outbreak. As these cases progress, the cumulative number of cases with severe respiratory illness will increase, potentially stressing the critical care system and leading to a sustained need for *emergency mass critical care* (EMCC) for weeks to months. Sustained EMCC can lead to depletion of critical care resources, such as mechanical ventilators, specially trained staff, antibiotics and antivirals, and ICU beds.⁵ Thus, the unique issues associated with sustained EMCC have led to improved planning for a response to a bioterrorism or emerging infectious diseases outbreak.^{89,90}

Recent consensus statements have recommended special critical care preparedness to include ICU capacity expansion, critical care resource storage, and the coordination of critical care across communities to a regional and statewide level.^{89,90} Capacity for critical care should be approximately three times normal ICU capacity, with all critically ill patients to be located in acute care hospitals (less severely ill patients will be diverted to alternative sites within the community). Each hospital should have enough supplies for 10 days for each critically ill patient along with plans to have expanded care by noncritical care specialists in the case of a shortage.⁹¹ ICU admission should be limited to the most severely ill. Most importantly, establishment of a triage mechanism is required for the allocation of scarce resources in sustained EMCC, with the most identified critical resource being mechanical ventilation and medical oxygen.⁹² This triage mechanism shifts the focus of critical care from optimal care of the individual to optimal care for the population and would identify critically ill patients who may not get specific scarce resources during a period of limited supply in an outbreak. It would include inclusion and exclusion criteria for ICU admission along with a triage scoring mechanism for patient assessment. The Sequential Organ Failure Assessment score is valuable, due to its value in sequential assessments and its ease of use given its lower reliance on laboratory data. Additional triage scoring systems may be warranted in future outbreaks as disease and outbreak conditions change.

Key Points

- Bioterrorism and emerging infectious diseases present unique and different diagnostic and treatment challenges.
- Category A agents are considered the highest risk to the public and national security for the following reasons: (1) easy person-to-person spread; (2) high mortality; (3) major public health impact causing panic and social disruption; and (4) requirement for specific and specialized public health emergency response (e.g., public prophylaxis or protective equipment). Diseases caused by these agents initially present with a nonspecific prodrome that develops into severe disease with specific epidemiologic hallmarks.
- Category A agents are anthrax, smallpox, plague, tularemia, botulism, and viral hemorrhagic fevers (e.g. Ebola, Lassa).
- Category B agents are diverse but carry lower morbidity and mortality, with some having few to no pulmonary manifestations.
- Category C agents have the potential for future use as bioterrorism agents.
- Early recognition relies on the astute clinician, with early involvement of public health and institutional infection control personnel to reduce spread to health care workers and the community.
- Aggressive supportive care is the mainstay for all critically ill patients infected with a bioterrorism agent. Targeted therapy is under development.
- For inhalational anthrax, raxibacumab, a human IgG1 monoclonal antibody directed against *B. anthracis* protective antigen, has been approved for use and should be used in combination with antibiotics when

the diagnosis of inhalation anthrax is suspected or confirmed.

- During an outbreak of a category A agent, emergency mass critical care for a sustained period may be required, leading to depletion of critical patient care resources. With emergency mass critical care, the focus of critical care shifts from optimal care of the individual to optimal care for the population. Predictive mortality scores are recommended for appropriate triage of the critically ill.

INTRODUCTION

Asthma is a common disease whose prevalence has increased throughout the world for several decades. For many years the major focus of asthma investigations and treatment was on allergic mechanisms. More recently, studies of the epidemiology, natural history, and pathogenesis have clearly demonstrated that asthma is a heterogeneous disease, with multiple etiologies and contributing cofactors, complex pathobiologic mechanisms, and different molecular phenotypes. Understanding these differences is critical for developing therapeutic strategies that will be effective for the various phenotypes of asthma.

EPIDEMIOLOGY

Asthma is common and its prevalence has been steadily increasing over time. In the United States, the prevalence and severity of asthma are highest in certain vulnerable populations including children, people living below the

poverty level, and specific minority groups (Puerto Ricans and black, non-Hispanic Americans). Although a family history of allergy is the strongest risk factor for asthma, early life infections are important cofactors in at least two ways. On one hand, the increasing prevalence of asthma may relate to the success of domestic hygiene in reducing the rate of exposure to bacterial products or changing the commensal microbiome in early childhood, which would otherwise consolidate antibacterial rather than allergic immune responses. On the other hand, viral respiratory infections in early childhood are thought to increase the risk for wheezing illnesses and asthma over time. A range of other exposures have been identified as risk factors for asthma, including intrauterine exposures, prematurity, breastfeeding, diet (especially vitamin intake), stress, exposure to other children, obesity, air pollution, antibiotic use, acetaminophen use, and occupational exposures. Ultimately, the natural history of asthma is heterogeneous; however, certain general patterns are common and the type of asthma that predominates in those who have their onset in childhood, teen years, and adult years may differ.

Figure 41-1 Prevalence of current asthma in the United States. Data are based on the National Health Interview Survey over two periods that used different case definitions (1980-1996 and 2001-2010). Percentages are age adjusted to the 2000 population. Blue lines connect actual data estimates, and gray lines show a modeled trend estimate. The prevalence of asthma in the United States has increased over both time periods. (From Moorman JE, Akinbami LJ, Bailey CM, et al. National surveillance of asthma: United States, 2001–2010. *Vital Health Stat* 3 Nov(35), 1–67, 2012.)

METHODS

For studies of the epidemiology of asthma, definition of asthma remains a critical issue. Options for case definition by questionnaire include assessment of asthma symptoms, use of asthma medications, self-report of asthma, and report of physician-diagnosed asthma. These questionnaire data may be complemented by lung function testing or measurement of bronchial hyperresponsiveness.¹ In general, self-report of asthma symptoms yields higher prevalence estimates than report of asthma diagnosis.

PREVALENCE

In the United States, the overall prevalence of asthma has risen inexorably between 1980 and 2011, even after accounting for changes in the definition of current asthma in *National Health Interview Survey* (NHIS) questionnaires (Fig. 41-1). Since 2001 the estimate of asthma prevalence has been based on the following questions, “Have you ever been told by a doctor or other health professional that you had asthma?” to estimate lifetime prevalence and then “Do you still have asthma?” to estimate current prevalence. In 2012, overall lifetime prevalence of asthma was 13.0% and current prevalence of asthma was 8.3%.^{1a}

In addition to being a common diagnosis across the entire U.S. population, there are marked and persistent differences in asthma prevalence across specific subgroups of the U.S. population, making asthma extremely common in certain vulnerable populations (Fig. 41-2). In 2012, current asthma prevalence was very high in black non-Hispanics (11.9%), those of Puerto Rican heritage (18.8%), and among those living below the poverty threshold (12.4%).

Current Asthma Prevalence in 2012 NHIS Data (Percent of US population)

Figure 41-2 Current asthma prevalence in the United States by age, gender, ethnic group, and income. Asthma prevalence is shown as a percentage of the U.S. population for different groups. Asthma prevalence is highest in certain vulnerable populations including children, Puerto Ricans, non-Hispanic blacks, and those living below the poverty level. (Data from the 2012 National Health Interview Survey as compiled by the Centers for Disease Control and Prevention on 3/5/2014 and posted at <http://www.cdc.gov/asthma/nhis/2012/table4-1.htm>.)

Current asthma prevalence also was higher among children (9.3%) than adults (8.0%) and among females (9.5%) than males (7.0%) overall, although the female-to-male balance changes over development with asthma less common in females than males during childhood (age younger than 18, 8.6% vs. 10%, respectively) but more common in females than males during adulthood (age 18 or older, 9.8% vs. 6%, respectively). These imbalances in prevalence among males and females, adults and children, ethnic groups, and poverty levels have not changed since 2001.

Internationally, the prevalence of asthma varies dramatically, with particularly high rates in specific, developed countries including the United Kingdom, New Zealand, Australia, the United States, and Canada (Fig. 41-3). Furthermore, as in the United States, the international prevalence is increasing over time.² Two large multinational studies have systematically assessed the worldwide prevalence of asthma in adults³ and children.⁴ The *International Study of Asthma and Allergies in Childhood* (ISAAC) study used a physician diagnosis and the presence of asthma-like symptoms in a validated questionnaire. In its first iteration, ISAAC Phase I studied 156 centers in 56 countries cross-sectionally during the period 1992-1996.^{5,6} This study confirmed the great variability in asthma prevalence that was inferred from the smaller studies that preceded it, with more than a 20-fold difference in prevalence between centers. However, it also found that some low- and middle-income

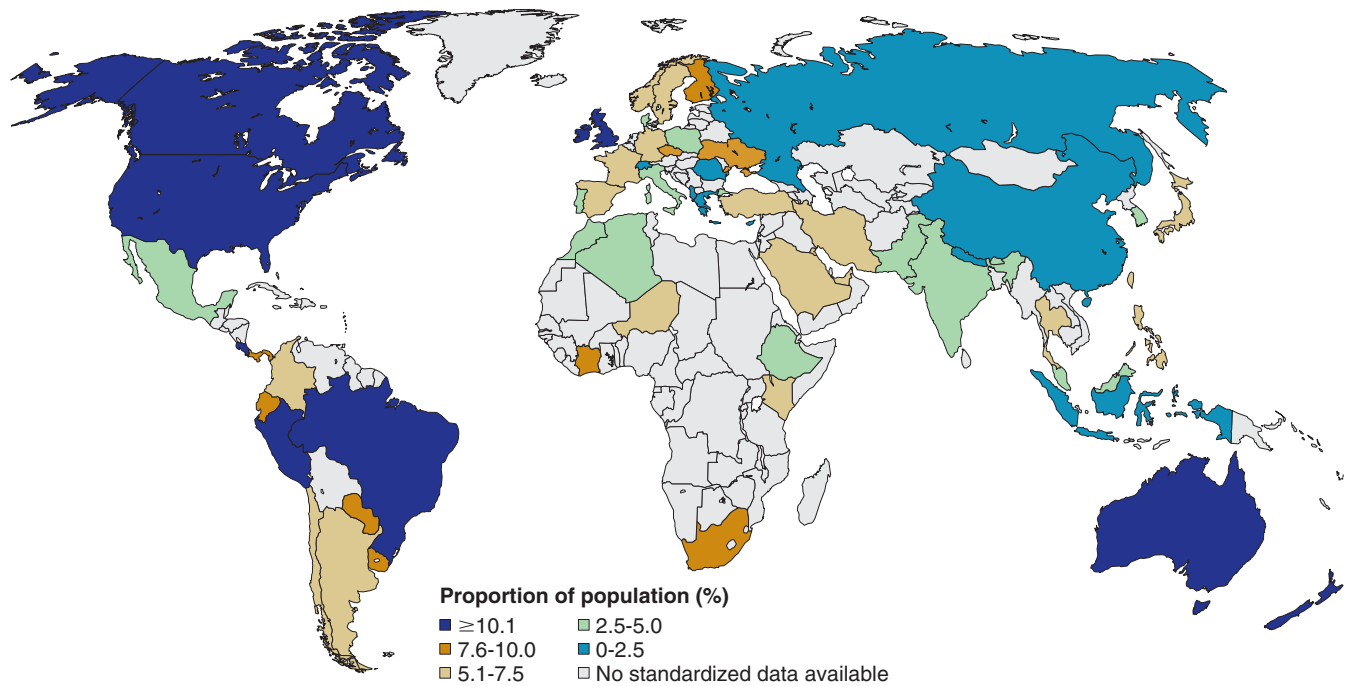

Figure 41-3 Estimated worldwide prevalence of clinical asthma. Prevalence data are estimates reflecting 50% of the prevalence of wheezing symptoms over a 12-month period in children from a range of studies, based on data on the relationship between wheezing symptoms and clinical asthma from other studies. (From Masoli M, Fabian D, Holt S, Beasley R: The global burden of asthma: executive summary of the GINA Dissemination Committee report. *Allergy* 59(5):469–478, 2004.)

countries had a prevalence of asthma symptoms that was similar to those in Western, developed countries. Thus the geographic trends are not absolute. ISAAC confirmed the overall increase in asthma prevalence on repeated evaluation from its Phase I period (1992-1996) to its Phase III period (2000-2003). However, these time trends in asthma symptom prevalence showed different regional patterns.⁷ With the exception of India, all of the countries with very low symptom prevalence rates at first evaluation reported increases in prevalence. However, in English-language developed countries, in which asthma prevalence was already high, there was little further increase. The *European Community Respiratory Health Survey* (ECRHS) used a questionnaire with seven questions relating to the 12-month prevalence of symptoms of asthma and studied representative samples of 20- to 44-year-old men and women in 48 centers, predominantly in Western Europe.⁸ Although the ECRHS included data from fewer countries than ISAAC and did not distill the broader set of questions into simple overall prevalence data, there was relatively good agreement between ISAAC and the ECRHS with respect to the prevalence of asthma symptoms across the 17 countries that both studies sampled.⁹

MORTALITY

Death from asthma was once thought to be so uncommon as to prompt Osler's adage that "the asthmatic pants into old age"¹⁰; nonetheless, data from the World Health Organization suggest there are 250,000 asthma-related deaths each year worldwide.¹¹ Although asthma mortality has historically increased in parallel with asthma prevalence in

many countries, the countries with the highest rates of death in the WHO report were not necessarily those with the highest prevalences, suggesting that poor access to care and essential medications are additional contributing factors to mortality. In specific instances, certain medications have also been suspected of contributing to asthma mortality. The event that initially attracted attention to asthma mortality was a dramatic, abrupt increase in asthma deaths in the 1960s, especially in the British Isles, Australia, New Zealand, and Norway.¹² In these countries, asthma mortality increased twofold to tenfold in less than 5 years. This increase was attributed to use of a high-dose preparation of a highly potent, nonselective inhaled β -agonist, isoproterenol, and mortality fell following the preparation's withdrawal. A second, even more dramatic increase in asthma mortality in New Zealand in the 1970s was again attributed to sales of a unique β -agonist, fenoterol.¹³

In the United States, asthma mortality has been assessed over time using the Mortality Component of the National Vital Statistics System. These data indicate an increase in asthma mortality from 14.4 per 1 million population in 1980 to 21.9 per 1 million in 1995.¹⁴ Since 1995, asthma mortality in the United States appears to have decreased to 17.2 per 1 million persons in 1999,¹⁴ and decreased further to 15 per 1 million persons in 2009.^{15a} However, as is true for asthma prevalence, asthma mortality disproportionately affects black Americans (38.7 per 1 million persons in 1999)¹⁴ and those of Puerto Rican heritage (40.1 per 1 million).¹⁵ It is not known whether high mortality among black and Puerto Rican Americans relates solely to societal factors, such as access to health care, insurance coverage, and access to medication or asthma education, or whether

specific environmental or genetic influences differentially affect these ethnic groups.

RISK FACTORS

Allergy

The strongest risk factor for asthma is a family history of atopy.^{16,17} This increases the risk of developing allergic rhinitis by fivefold and the risk of asthma by threefold to fourfold.¹⁸ In children 3 to 14 years old, both positive skin tests and increases in total serum IgE are strongly associated with asthma.^{19,20} Serum IgE also correlates strongly with bronchial hyperresponsiveness.²¹ In adults, the odds of having asthma increase with the number of positive skin tests to common allergens.²²

Because much allergic asthma is associated with sensitivity to allergens of the indoor environment and because Western styles of housing favor greater exposure to indoor allergens, initial attention focused on increased exposure to these allergens in infancy and early childhood as a primary cause of the rise in asthma. Specific allergens of interest have included house dust mite,^{23,24} dog and cat dander,²⁵ and cockroach allergen,²⁶ especially in the inner city. These and other observations strongly support the conclusion that allergen controls should be valuable in the treatment or prevention of asthma.^{27,28} However, even after more than 50 individual studies of allergen control, the conclusions drawn from those studies via meta-analyses and expert review have been at odds and hotly debated.^{29,30}

“Hygiene Hypothesis.” One compelling hypothesis for the cause of the increase in asthma and allergies in Westernized countries is the “hygiene hypothesis.” This holds that the rise in allergies in children is an unintended consequence of the success of domestic hygiene in reducing the rate of infections or exposure to bacterial products in early childhood. This hypothesis was put forward to explain the inverse relationship between hay fever and family size.³¹ The hypothesis was cited later when children raised in West Germany were found to have significantly higher rates of asthma and hay fever than did those raised in communist East Germany³² despite its more severe pollution from heavy industrialization and coal burning.³³ In these studies, children who lived on farms had a lower prevalence of hay fever and asthma than their peers who did not live in an agricultural environment. The reduction in risk was stronger for children whose families were running the farm on a full-time basis, and stronger yet if the farm included livestock.^{34,35} Factors related to environmental influences, such as increased exposure to bacterial compounds in stables, may prevent the development of allergic disorders in children. Continual long-term exposure to stables until age 5 was associated with very low rates of asthma (0.8%), hay fever (0.8%), and atopic sensitization (8.2%).³⁶ Follow-up studies of the protective effects of farm life have yielded fascinating findings. One study showed that endotoxin levels in samples of dust from the children’s homes, regarded as a marker of environmental exposure to microbial products, were inversely related to the presence of hay fever, atopic asthma, and atopic sensitization.³⁷ Another study employing two cohorts found that children who lived on

farms had lower prevalences of asthma and atopy and were exposed to a greater variety of environmental microorganisms than the children in the reference groups and that the diversity of microbial exposure was inversely related to the risk of asthma.³⁸

Human Microbiome

One potential link between changes in hygiene and allergic disease is the effect that “improved” hygiene may have on our indigenous microbiota and the role this microbiota may play in shaping our immune system.^{39–43} The biologic model most commonly cited to explain this association is that early-life exposure to factors that promote Th1 immunity are necessary to blunt exuberant *type 2 T helper* (Th2) immunity. Animal studies provide some support for this model.^{44–52} However, the results of human trials designed to treat or prevent asthma and allergy through “probiotic” live bacteria administration have thus far been mixed.^{53–55} Thus additional studies will be required to determine whether clinically relevant interventions that leverage the proposed role of the human microbiome in shaping allergic responses can be fashioned.

Respiratory Viral Infections

In parallel with, and distinct from, the emergence of the “Hygiene Hypothesis,” there has been significant progress in documenting and understanding the role that viral respiratory tract infections play in the development of asthma. A population-based study reported that a history of bronchiolitis or croup in early childhood was a predictor of increased bronchial responsiveness and of atopy in later years.⁵⁶ In a prospective, longitudinal study of children born to allergic parents, *upper respiratory infections* (URIs) were noted 1 to 2 months before the onset of allergic sensitization.⁵⁷ Children who have *lower respiratory tract infections* (LRI) caused by *respiratory syncytial virus* (RSV) are at a threefold to fourfold risk of subsequent wheezing during the early school years.^{58–61} Surprisingly, the presence of rhinovirus during wheezing episodes is an even stronger predictor of subsequent asthma.^{62,63} In some studies, the association between viral LRIs and subsequent asthma depends on concurrent atopic disease, suggesting that an interaction between atopic predisposition and LRI at an early developmental stage may be critically important.⁶²

One factor that complicates the relationship between early wheezing with LRIs and the risk of subsequent asthma is that longitudinal studies of the natural history of wheezing illnesses have identified inconsistent relationships between early wheezing phenotypes and the ultimate development of asthma. The natural history of asthma is discussed in more detail in the next section of this chapter, but, briefly, some children who have wheezing illnesses before age 3 continue to wheeze at age 6. However, not all children fit this “persistent-wheezing” pattern. Similarly, there are children who wheeze at age 6 who never had wheezing illnesses before age 3. Thus a propensity for wheezing can be transient and the causes may be different at different ages. For example, factors associated with wheezing before age 3 include small airway caliber and maternal smoking, whereas factors associated with wheezing after age 3 include elevated serum IgE and a maternal history of asthma.⁶⁴ Furthermore, it is possible that viral LRIs do not

induce asthma but rather unmask a predisposition to predominant Th2-like responses already present at the time of the infection⁶⁵ and which manifest later as asthma. The recent availability of specific therapies for the treatment and prevention of RSV infection in early childhood may provide the tools for future studies to test whether viral LRIs actually cause persistent wheezing and asthma.⁶⁶

Atypical Bacterial Infections

Although typical bacterial infections are not thought to cause asthma, at least two bacterial causes of “atypical” pneumonia have been implicated in the development of chronic wheezing illnesses, *Chlamydia pneumoniae* and *Mycoplasma pneumoniae*. Both commonly infect the airway epithelium, can become chronic, and stimulate local inflammatory reactions. There is some *polymerase chain reaction* (PCR) evidence that *M. pneumoniae* or *C. pneumoniae* is more common in the airway of patients with chronic stable asthma compared with healthy controls and that their presence is associated with an increase in tissue mast cells.⁶⁷ Other studies have found that these atypical infections are associated with asthma exacerbations.⁶⁸ Both organisms are sensitive to macrolide antibiotics, and several studies have evaluated the utility of macrolides in patients with chronic asthma with variable results. A randomized trial of clarithromycin for the treatment of suboptimally controlled asthma showed no improvement in asthma control, whether or not *M. pneumoniae* or *C. pneumoniae* was detected by PCR in endobronchial biopsies.⁶⁹ Another study showed that azithromycin did not reduce exacerbations overall in severe asthma, but a prespecified subgroup analysis showed improvement in the group with noneosinophilic asthma by sputum analysis.⁷⁰ This result leaves open the question as to whether any beneficial effect of macrolides is mediated by antibacterial or anti-inflammatory activity of these drugs.

Air Pollution

Although it is widely accepted that air pollution can exacerbate preexisting asthma,^{71,72} it has been more difficult to demonstrate that air pollution can contribute to the development of asthma. In principle, exposure of the lung to air pollution could increase local oxidative stress, induce or modify local inflammation, enhance sensitization to allergens, impair lung development, or injure small airways. However, epidemiologic evidence for an association between ambient levels of air pollutants and prevalent or incident asthma has yielded mixed results.⁷³ Nonetheless, several recent studies focused specifically on asthma incidence and prevalence by proximity to heavy automobile traffic and suggested that exposure to respirable particulate matter and NO₂ in this setting are both associated with the future development of asthma.^{72,74-79}

Other Early-Life Factors

Other early-life factors that influence the risk of asthma are exposures in utero, perinatally and in early childhood. Intrauterine risk factors include growth rates (both high and low),^{80,81} dietary vitamins D and E deficiency,^{82,83} exposure to microbial products,⁸⁴ parental smoking,⁸⁵ and parental stress.⁸⁶ Perinatal risk factors associated with asthma include prematurity⁸⁷ and chorioamnionitis.⁸⁸

Finally, early childhood risk factors associated with asthma include a shorter period of breastfeeding,^{89,90} obesity,⁸⁰ absence of older siblings or daycare attendance,⁹¹ bacterial colonization of the airways in early childhood,⁹² antibiotic use,⁹³ and acetaminophen use.⁹⁴

Occupational Exposures

Finally, occupational exposures constitute an important risk factor for a specific subset of patients. Asthma induced by occupational exposures accounts for up to 17% of all adult-onset asthma.⁹⁵ A full description of the occupational exposures that can cause asthma is beyond the scope of this chapter because the known exposures number in the hundreds. However, in general, occupational asthma can either result from immunologically mediated sensitization to occupational agents (i.e., sensitizer-induced occupational asthma) or from exposure to high concentrations of irritant compounds (i.e., irritant-induced occupational asthma) (see Chapter 72).

NATURAL HISTORY

The natural history of asthma is heterogeneous with different patients following different disease courses. In general, symptoms can begin at any age, although the type of asthma that predominates in those who have their onset in childhood, teen years, and adult years may differ. Over time, the symptoms of asthma can remit in any given patient, especially in childhood. Alternatively, the symptoms and the finding of airflow obstruction can persist or even worsen progressively in some patients. Other patients can be apparently well at most times but suffer from periodic worsening or exacerbations. From a population-based perspective, a relatively small but important subgroup of patients with asthma can suffer significant morbidity and some are at risk for dying from asthma.

Neonatal Period

A predisposition to asthma may begin as early as the neonatal period. The immunologic milieu at the fetal-maternal interface is skewed toward a Th2 phenotype, and this immune bias is carried into neonatal life.⁹⁶ Unless the pattern of immune response in the airways is “re-programmed” toward a Th1 pattern, the infant may have a prolonged high-risk window for allergic sensitization to aeroallergens.⁹⁷

Childhood

Patterns of wheezing in early childhood have been intensively studied in longitudinal cohorts.^{64,98} The Tucson Children’s Respiratory Health Study⁶⁴ found that 48% of children had at least one wheezing illness at some point in the first 6 years of life, 34% had at least one wheezing illness before age 3 (defined as early wheezing), and approximately half of these children continued to have at least one wheezing illness at age 6. In the remainder of children with wheezing episodes before age 3, these episodes were transient and resolved before age 6. Finally, approximately 15% of children presented with late-onset wheezing, defined as wheezing illnesses with onset at age 6. As described earlier, most of the early wheezing illnesses (before age 3) can be ascribed to viral respiratory infections such as RSV

or rhinovirus and do not necessarily reflect atopy.⁹⁹ In addition, transient early wheeze was associated with maternal smoking. However, wheezing at age 6, whether “persistent” or “late-onset,” was associated with atopy. Furthermore, children who had either “persistent” or “late-onset” wheezing at age 6 were more likely to go on to wheeze later in life and be diagnosed with asthma. The risk for persistence rather than remission after age 6 appears to be associated with severity of airflow obstruction and the degree of allergen sensitization.¹⁰⁰ The British Avon Longitudinal Study of Parents and Children provided some additional detail to the categories of childhood wheezing illnesses by defining “intermediate-onset wheeze” (defined as onset of symptoms after 18 months) and “early prolonged wheeze” (defined as onset in the first year of life but remission at 69 months).⁹⁸

Atopic or Allergic March

The terms “atopic march” and “allergic march” are synonyms that refer to a characteristic pattern of atopic disease development during infancy and childhood.^{101,102} The most common pattern begins with atopic dermatitis or eczema in the first year of life, sometimes associated with food intolerance or food allergy, followed by rhinoconjunctivitis, and/or wheezing illnesses that are ultimately diagnosed as asthma. Thus the natural history of atopic disease, more generally, may follow a specific pattern of organ-specific development, which suggests a stereotyped set of underlying cellular and molecular mechanisms.¹⁰³

Teenage Years

After puberty, the demographics of patients with prevalent asthma switches from a male predominance to a female predominance, which suggests a change in the nature of incident cases of asthma. One straightforward inference would be that some incident cases of asthma in girls during teenage years relate specifically to hormonal factors. This is a compelling hypothesis and there are some data that provide clues to potential mechanisms,¹⁰⁴⁻¹⁰⁶ but specific hypotheses are difficult to test and establish in clinical studies. Nonetheless, these observations invite speculation that the onset of asthma in specific phases of life may reflect different underlying biologic underpinning or different endotypes of asthma.

Remission

Long-term follow-up of a population-based birth cohort of more than 1000 children born in Dunedin, New Zealand over a 12-month period in 1972-1973 who were evaluated annually to age 26 has provided a clear picture of the natural history of the disease.¹⁰⁷ Just over half the children (51%) reported wheezing at more than one assessment, confirming the high prevalence of asthma in New Zealand. Wheezing persisted until adulthood in 15%, whereas wheezing appeared and remitted in 27%. This remission was often unsustained, however, for wheezing recurred by age 26 in nearly half of those in whom it had remitted. This finding echoes the findings of 15 earlier studies of the natural history of asthma, showing that about 50% of adults who recall having childhood asthma continue to have symptoms.¹⁰⁸ Risk factors associated with greater likelihood of persistence of asthma into adulthood include sensitization to house dust mites, lower FEV₁, airway hyper-

responsiveness, female gender, and smoking at the age of 21 years.¹⁰⁷ Whether “spontaneous remission” truly reflects disappearance of the eosinophilic, lymphocytic bronchial inflammation of asthma has been questioned. Even in patients with complete absence of symptoms while taking no asthma medications for at least 12 months, the fraction of nitric oxide in exhaled gas is elevated, airway responsiveness is increased, and bronchial biopsies show increases in eosinophils, T cells, mast cells, and increased subepithelial fibrosis.^{109,110}

Progressive Airflow Obstruction

Longitudinal studies have shown that people with asthma have greater rates of decline in pulmonary function than healthy nonsmokers, and asthmatic smokers have greater rates of decline than healthy smokers.^{111,112} Furthermore, many nonsmoking asthmatics have severe, irreversible airflow obstruction.^{113,114} The progressive narrowing of the airways in chronic asthma is hypothesized to result from the deposition of collagen and growth of vessels, smooth muscle, secretory cells, and glands, presumably mediated by the products of inflammatory cells activated in the airways.^{115,116} Nonetheless, it is not possible to prove that this “airway remodeling” is the cause of progressive airflow obstruction in asthma.

Adulthood

Because many adults with chronic asthma had the onset of symptoms during childhood,¹¹⁷⁻¹¹⁹ understanding the biologic events underlying the development and the prevention of asthma during childhood will likely make a significant impact on the prevalence of asthma in adults as well. However, even though many adults with asthma had asthma during childhood, adult asthma is particularly heterogeneous. The female predominance in asthma prevalence that first appears in teenage years continues in adult asthma, suggesting that a significant proportion of adults with asthma share the common underlying factors of teenage-onset asthma. Finally, asthma symptoms can begin *de novo* in an adult. Some of these patients have clear-cut atopy, but others have more predominantly nonatopic features. In some instances, the onset of wheezing is attributed to a specific acute respiratory illness that became persistent. In others, it is possible that atopy and wheezing illnesses as a child were modest and subclinical.

Asthma in the Elderly

If asthma is present in an adult, it will often remain as that adult ages. Surprisingly, new-onset asthma can also arise in the elderly. One retrospective cohort study of residents of Rochester, Minnesota reported that the incidence of new-onset asthma after age 65 was 95/100,000.¹²⁰ In this age group, misdiagnosis of asthma (often as COPD) and undertreatment appear to be common.^{121,122} Furthermore, elderly patients with asthma are more likely than younger patients to have fixed airflow obstruction.¹²³ Mortality rates from asthma appear to be higher in the elderly because NHIS data from 2001-2003 indicate that the age-adjusted rate of mortality was 10.5 per 100,000 among people older than 65. All other adult age groups had asthma-specific mortality rates less than 2.2 per 100,000.¹²⁴ However, these NHIS data appear to contrast with those of the

Rochester, Minnesota retrospective cohort study described earlier, which found no difference in mortality between elderly patients with asthma and similarly aged historical control subjects.¹²⁰ The term “intrinsic asthma,” often used to describe nonatopic reversible bronchoconstriction, has traditionally been associated with asthma in the elderly,¹²⁵ and more than 60% of elderly patients in one study reported the first onset of asthma symptoms following a URI.¹²⁰ However, at least one study has shown positive skin reactivity to one or more common allergens in almost two thirds of elderly asthmatic patients.¹²⁶

MOLECULAR AND CELLULAR BASIS OF ASTHMA

Type 2 immune responses in the lower airway are the central immunologic abnormality in asthma. Type 1 and type 2 immune responses differ in how they are induced and by the types of effector cells and molecules they employ.¹²⁷ For example, type 1 immune responses are mounted against intracellular bacteria, viruses, and protozoa and are mediated by Th1 CD4⁺ cells, cytotoxic CD8⁺ T cells, and IgG antibodies. Type 1 responses can also be inappropriately mounted against self-antigens, and this is one mechanism of autoimmune disease. In contrast, type 2 immune responses usually arise in response to helminth and parasite infections and are mediated by Th2 CD4⁺ cells and IgE. Type 2 responses can also be inappropriately mounted against innocuous environmental antigens resulting in allergy. Th2 CD4⁺ cells are characterized by high expression of the transacting T-cell-specific transcription factor GATA-3 and by secretion of type 2 cytokines (*interleukin* [IL]-4, IL-5, IL-9, and IL-13).¹²⁸ An excess of type 2 cytokines in the lower airway will promote IgE-mediated hypersensitivity, activate epithelial cells, mediate inflammatory cell influx to the airway, and cause remodeling responses in the epithelium and subepithelial matrix.^{129,130} This cascade of inflammatory events downstream of type 2 cytokines explains much of the pathology underlying the key clinical features of asthma (airway hyperresponsiveness, airflow obstruction, and mucus secretion).

INITIATION OF ALLERGIC LOWER AIRWAY RESPONSES AND ASTHMA

An accepted view now is that environmental stimuli in early childhood activate airway epithelial cells to initiate allergic airway responses and asthma in children who are susceptible because they have preexisting atopy, specific genetic risk factors, and other less well-understood vulnerabilities. How atopy and viral airway infections interact to initiate type 2 immune responses is incompletely understood. It has been postulated that communication between cells in the airway epithelium and cells in the underlying mesenchyme/submucosa is a fundamental mechanism of asthma.^{131,132} (Fig. 41-4). Environmental stimuli that can activate epithelial cells include oxidants (cigarette smoke, car exhaust pollutants), aeroallergens, and microbial infections, especially viruses. Airway epithelial cells express multiple pattern recognition receptors to detect and respond

Figure 41-4 Generation of Type 2 immune responses in the lower airway. The airway epithelium is activated to release thymic stromal lymphopoietin (TSLP), IL-25, and IL-33. TSLP mediates maturation and migration of dendritic cells to local lymph nodes, where they have the following effects: (1) generation of Th2 cells from Th0 cells; (2) generation of IL-4-secreting T_H cells; and (3) B cell isotype-switching to IgE, which arms mast cells and basophils for allergen-specific activation. IL-33 promotes IL-4 release from basophils, and IL-25 and IL-33 promote IL-5 and IL-13 release from innate lymphoid type 2 (ILC2) cells and Th2 cells (see text for details). T_H, T follicular helper cells. (From Locksley RM: Asthma and allergic inflammation. *Cell* 140(6):777–783, 2010.)

to danger signals, such as *pathogen-associated molecular patterns* (“PAMPs”) on microbes or *damage-associated molecular patterns* (“DAMPs”) released by endogenous cells during periods of inflammation or cellular stress. Other pattern recognition receptors on airway epithelial cells include *Toll-like receptors* (TLRs) and receptors for *alarmins*, such as uric acid and adenosine triphosphate, which are endogenous molecules that signal damage. Activation of pattern recognition receptors on airway epithelial cells can trigger release of a variety of cytokines, chemokines, antimicrobial peptides, lipid mediators, nitric oxide, and reactive oxygen species. These inflammatory mediators have multiple consequences, including recruitment of circulating leukocytes to the airway, regulation of airway tone, regulation of airway secretions, and promotion of antimicrobial and antiviral activity. The release of epithelial cytokines, particularly IL-25, IL-33, and *thymic stromal lymphopoietin* (TSLP), appears to be the key upstream event that initiates type 2 immune responses and the allergic inflammatory environment in asthma.^{128,133} Specifically, IL-25, IL-33, and TSLP released from epithelial cells by allergenic stimuli target resident hematopoietic cells to induce the influx of inflammatory cells and the activation and mobilization of dendritic cells. Dendritic cells are specialized immune cells that use the class 2 *major histocompatibility complex* (MHC) system to mediate T helper cell responses to foreign proteins such as aeroallergens.¹³⁴ Dendritic cells are required for the differentiation of naive T cells into T helper subsets including Th2 cells. Immature dendritic cells from the bone marrow home to the airway under the influence of epithelial cell signals. Once in the airway mucosa, dendritic cell projections interdigitate between epithelial cells and form tight junctions with them,

maintaining the integrity of the epithelial barrier. In this location, dendritic cells sample inhaled antigens, process them to linear peptides, and present them on their cell surface as part of the class II MHC heterodimer complex. Epithelial cytokines, especially TSLP, promote mobilization of dendritic cells to local draining lymph nodes, where they activate naive CD4⁺ T cells to an IL-4-competent state. These IL-4-competent T cells in lymph nodes migrate to B-cell zones, where they differentiate into *T follicular helper* (T_{FH}) cells. In addition, they move to the circulation to complete maturation as Th2 cells (see Fig. 41-4).¹²⁸ Whereas IL-4-secreting developing T_{FH} cells in parafollicular B-cell areas and germinal centers mediate IgE switching in B cells, Th2 cells that migrate to the airway epithelium and the subepithelial mucosa secrete IL-5 and IL-13 to mediate the characteristic pathologic features of asthma, including eosinophilic inflammation and remodeling changes in the epithelium and submucosa.¹³⁰

The aeroallergens of relevance to asthma such as pollens, house dust mite proteins, and proteins from furred animals are considered innocuous and should induce immune tolerance when inhaled. The breach in tolerance that takes place in asthmatic airways is incompletely understood. Some aeroallergens have physical properties that allow them to be aerosolized and reach conducting airways. Some also have protease activity that equips them to penetrate airway mucus barriers. Still others have molecular mimicry properties that trigger innate pattern recognition receptors on airway epithelial cells and other antigen-presenting cells. For example, house dust mite allergens have a papain-like cysteine protease and a lipid-binding MD-2 molecular mimetic capable of augmenting TLR4 signaling,¹³⁵ while many other allergens contain chitin, which induces a leukotriene-mediated infiltrate of eosinophils and basophils and drives alternative activation of macrophages.¹³⁶

Breach in tolerance may also involve cooperative pathologic behavior between epithelial cells and dendritic cells. In mouse models, dendritic cells do not always recognize inhaled allergens. Rather, activated epithelial cells use a pattern recognition molecule such as TLR4 to sample allergens such as house dust mite protein and then orchestrate dendritic cell responses (recruitment, activation, lymph node migration) that lead to sensitization.¹³³ These findings provide a framework for how an environmental stimulus might direct epithelial and dendritic cell responses in the airway toward allergic responses. Normal tolerance in the airway may also be breached because *T regulatory cell* (Treg) function is compromised. Tregs may induce peripheral tolerance to allergens through direct interactions with dendritic cells or competition with naive T cells for growth and differentiation factors.¹³⁷ Another possible mechanism is that Tregs characteristically secrete IL-10 and *transforming growth factor* (TGF)- β , cytokines that have multiple activities relevant to tolerance, including synthesis of noninflammatory IgG4 and IgA isotypes and regulatory effects on T cells and dendritic cells. Although specific evidence for Treg cell dysfunction in asthma is lacking, the central role of Treg cells in controlling immune responses is well recognized in human disease.¹³⁸

Viral infections are among the most important of the environmental stimuli that are implicated in asthma initiation. Airway epithelial cells are considered active sentinels

and master coordinators of antiviral responses in the lung. Airway epithelial cells are primed to produce *interferon* (IFN) and express hundreds of *IFN-stimulated genes* (ISGs) in response to viral infection. STAT1 is a key regulator of ISG expression, and ISGs encode proteins that inhibit viral production directly or indirectly by activating immune cells and killing infected host cells.¹³⁹ Because the functional level of antiviral responses correlates with the degree of host protection, it is possible that a deficiency of IFN makes some people susceptible to virus-initiated or virus-exacerbated asthma. Data from mouse models suggest that a deficiency of IFN signaling in airway epithelial cells compromises host defense against respiratory viruses,^{139,140} and data from these models and epidemiologic studies show that more severe viral infections are more likely to lead to asthma.¹⁴¹ Although some studies have shown a deficiency in IFN- β and IFN- λ production in response to rhinovirus infection in asthmatic airway epithelial cells,^{142,143} it is not yet established that a defect in IFN-dependent control of viral replication is a mechanism of asthma initiation or exacerbation.^{139,144}

ATOPY, ASTHMA, AND OTHER ALLERGIC DISEASES

Studies of the childhood origins of asthma reveal a sequence in which atopy arises first, followed by viral airway infections and then the onset of asthma.¹⁴⁵ Atopic illnesses in childhood include allergic rhinitis, atopic dermatitis, eosinophilic esophagitis, and asthma. Many children only develop one of these atopic diseases, which raises the possibility that atopy represents one hit along a multihit continuum with different hits resulting in different atopic diseases. For example, atopy combined with filaggrin mutations may be required to cause atopic eczema. In this instance, filaggrin dysfunction may alter the skin epithelial barrier in ways that promote eczema.¹⁴⁶ Atopy combined with mutations in TSLP may cause eosinophilic esophagitis. In this instance, TSLP dysfunction in esophageal epithelial cells may interact with T cells, basophils, or innate lymphoid cells to initiate eosinophilic esophageal disease.¹⁴⁷ Whereas genetic studies clearly point to mutations in the filaggrin and TSLP genes as susceptibility factors for eczema and eosinophilic esophagitis, respectively, the genetic pointers in asthma are toward IL-33 and its receptor (ST2, suppression of tumorigenicity 2).¹⁴⁸⁻¹⁵⁰ Thus atopy may be the core pathologic abnormality in a variety of allergic diseases, but each of these atopic diseases may require an additional and specific genetic susceptibility to confer organ-specific risk of disease.

IL-33/ST2 AXIS IN ASTHMA

IL-33 is an epithelial cell cytokine that is considered a key mediator of type 2 immune responses in asthma.¹⁵¹⁻¹⁵³ IL-33 is classified as a member of the IL-1 family of cytokines because it has an IL-1–type cytokine-signaling domain in its C terminal region.^{154,155} Unlike other members of the IL-1 cytokine family, IL-33 is active in its full-length form, although protease digestion of specific N terminal regions can increase its activity.¹⁵⁵ IL-33 triggers biologic responses in effector cells by assembling a heterotrimeric signaling complex with two receptor chains that comprise a

high-affinity primary receptor called IL1RL1 (better known as ST2) and a low-affinity coreceptor called IL-1RAcP.¹⁵⁶ In the airway, IL-33 localizes mainly to the nuclei of epithelial basal cells,¹⁵⁷ and this unusual cellular location reflects its dual roles. One role that depends on its nuclear localization is as a repressor of gene transcription; a second (better understood) role depends on its extracellular secretion and activity as a cytokine. The principal cytokine activity of IL-33 is to promote Th2 inflammation through release of Th2 cytokines by ST2-bearing cells. ST2 is expressed on a wide range of innate and adaptive immune cells, including CD4⁺ T cells, mast cells, basophils, and *innate lymphoid type 2* (ILC2) cells. ILC2 cells are recently characterized lineage negative IL-25R⁺ lymphoid cells.¹⁵⁸ Although CD4⁺ T cells are the dominant source of Th2 cytokines in the airway, the ILC2 cell is increasingly recognized as a rare but potentially important cellular source.

The emphasis on IL-33 as a key epithelial cell mediator of type 2 immune responses in asthma stems from multiple *genome-wide association studies* (GWASs) that have consistently found associations between asthma and genetic polymorphisms at the IL-33 locus and the ST2 locus.^{148,149,159,160} The ST2 gene locus encodes the *full-length ST2 receptor* (ST2L) and the *short soluble form of ST2* (sST2) that acts as a potent negative regulator of extracellular IL-33 activity. Interestingly, genetic polymorphisms in ST2 are associated with low levels of circulating sST2 and high numbers of peripheral blood eosinophils,¹⁶¹ so a relative deficiency in sST2 may be a mechanism of Th2-type inflammation. Thus the IL-33/ST2 axis in asthma is a complex signaling system in which regulation of IL-33, ST2L, and sST2 all contribute to net effects on type 2 immune responses in the airway. The genetic defects in IL-33 and ST2 identified in GWAS studies are presumed to result in net positive IL-33 activity. To date, the specific functional consequences of genetic mutations in IL-33 and ST2 are poorly understood, but additional mechanistic studies should clarify how these genetic abnormalities promote airway Th2 inflammation to cause asthma.

MECHANISMS OF PERSISTENCE OF ASTHMA

As described earlier, the initiation of asthma involves the development of type 2 immune responses to inhaled allergen in young children who have a family and personal history of atopy and who frequently have a history of respiratory tract infection. The mechanisms of persistent type 2 immune responses in asthma are not well understood. One possibility is that aberrant immune programs become fixed because they are established during critical time windows in early life when the immune system is plastic. In this window, it may be that epithelial cells are particularly susceptible to epigenetic changes that lead to persistent changes in cell behavior. Epigenetic changes include DNA methylation or post-translational modification of the amino acid tails of histones by acetylation, phosphorylation, methylation, sumoylation, or ubiquitylation.^{162,163} Because epigenetic changes persist in dividing cells, they provide a mechanism by which environmental factors can cause stable alterations in phenotype without changes in genotype. Most epigenetic changes take place prenatally and shortly after birth, which would coincide with the specific

time periods when individuals are most susceptible to environmental exposures that induce asthma. Although the epigenetic hypothesis is attractive, there is little direct evidence for it yet in asthma.

INFLAMMATORY MECHANISMS IN CHRONIC ASTHMA

Current concepts hold that upstream events in the airway epithelium involving master regulators such as IL-33 result in increased activity of type 2 cytokines in the airway, secreted mainly by CD4⁺ T cells, and driving a cascade of downstream events, including IgE-mediated hypersensitivity, activation of airway epithelial cells, chemoattraction of effector cells (mast cells, eosinophils, and basophils), and remodeling of the epithelium and subepithelial matrix (Fig. 41-5).

CD4⁺ T Cells

CD4⁺ T lymphocyte subsets are categorized on the basis of their cellular functions and capacity to secrete specific cytokines. CD4⁺ Th2 lymphocytes evolved to mediate type 2 immune responses to helminths and parasites, but they are also central to mechanisms of atopy and asthma. IL-4 is the most potent Th2 polarizing factor,¹⁶⁴ and Th2 cells secrete IL-4, IL-5, IL-9, and IL-13.¹²⁷⁻¹²⁹ There is evidence in human asthma for an excess of CD4⁺ Th2 lymphocytes in the airway. Lavage fluid from asthmatic subjects has increased numbers of T cells expressing mRNA for IL-4 and IL-5 (but not IFN- γ).¹⁶⁵ Subsequent studies have confirmed either an excess of Th2 lymphocytes or increases in Th2 cytokine transcripts, protein, or activity in the airway.^{166,167} CD4⁺ Th2 cells are not the sole source of Th2 cytokines because mast cells, basophils, and ILC2 cells also secrete these cytokines, but they do appear to be the dominant source in chronic established disease. CD4⁺ Th2 cells are CCR4⁺ and are responsive to CCL17 (also called thymus and activation-regulated chemokine, TARC), which is an epithelial cell-derived chemokine important for Th2 cell accumulation in the airway (see Fig. 41-5). CD4⁺ Th2 cells also display multiple other receptors, including CRTH2, ST2, TSLPR, and IL17BR, which means that they can also respond to PGD2, IL-33, TSLP, and IL-25, respectively.¹⁶⁸ IL-5 from Th2 cells promotes tissue eosinophilia, whereas IL-9 promotes mast cell hyperplasia, and IL-13 causes epithelial cell activation, as described earlier.

IgE-Mediated Hypersensitivity

As described previously, the production of allergen-specific IgE requires that allergens are taken up by dendritic cells or other antigen-presenting cells, which, in the presence of IL-4, present the processed antigens to naive T cells to direct them toward a Th2 cell phenotype. IL-4 also induces isotype switching in B cells, resulting in IgE production.¹⁶⁹ Notably, the IL-4-producing cells that interact with B cells in secondary lymphoid organs are T_{FH} cells, and not Th2 cells.¹⁷⁰ IgE has two IgE receptors—Fc ϵ RI and Fc ϵ R2. Fc ϵ RI is a high-affinity receptor found on mast cells and basophils.¹⁷¹ Fc ϵ R2 (CD23) is a low-affinity receptor found on epithelial cells, B cells, and myeloid cells.¹⁷² Antigen-induced aggregation of IgE bound to Fc ϵ RI stimulates mast cells to release diverse biologically active products. Preformed products in

Figure 41-5 Schematic depicting roles for the airway epithelium in the initiation and amplification of airway Th2 responses. IL-25 and IL-33 released by epithelial cells during initiating stimuli interact with lineage-negative IL-25R⁺ lymphoid cells, which also bear the ST2 receptor. Activation of these cells causes secretion of IL-5 and IL-13, which in turn activate the airway epithelium to release CC chemokines and other mediators, which recruit CD4⁺ T cells, eosinophils, and mast cells to promote and sustain Th2 inflammation and the asthma phenotype. SCF, stem cell factor; iH2, innate helper type 2 cells; ST2, suppression of tumorigenicity 2. (From Fahy JV, Locksley RM: The airway epithelium as a regulator of Th2 responses in asthma. *Am J Respir Crit Care Med* 184(4):390–392, 2011.)

cytoplasmic granules include histamine, serotonin, tryptase, chymase, carboxypeptidase A3, and proteoglycans (heparin and/or chondroitin sulfates). Other products are synthesized *de novo* and include lipid-derived mediators (PGD2, LTB4, LTC4, LTD4, and LTE4) and Th2 cytokines. Mediators are released within minutes of antigen exposure, and the aggregate response to mediators released shortly after antigen- and IgE-induced mast cell degranulation is called an immediate-hypersensitivity (“early-phase”) reaction.¹⁷³ This reaction includes airway smooth muscle contraction, heightened bronchovascular permeability, and increases in mucin secretion. The physiologic consequence is a decrease in airflow but can include hypotension and anaphylaxis if the immediate hypersensitivity response is systemic. Although the inflammation and functional changes associated with early-phase responses resolve within 1 to 3 hours, a second (“late-phase”) reaction can develop in some asthmatics, typically beginning 2 to 6 hours after exposure and lasting for 24 to 48 hours.¹⁷⁴ Late-phase responders are often studied in proof-of-concept studies of novel controller medications for asthma because a drug’s ability to inhibit late-phase responses to inhaled allergen is a good predictor of its efficacy in improving asthma control outcomes. For example, omalizumab is a recombinant humanized monoclonal antibody directed against IgE. In early proof of concept studies, omalizumab was shown to inhibit both early and late phase responses.¹⁷⁵ In subsequent clinical trials it was shown to decrease exacerbation rates in asthmatics.^{176,177}

Activation of Airway Epithelial Cells

Unbiased studies of gene expression in airway epithelial cells show a gene profile consistent with IL-13 activation.¹⁷⁸ Gene transcripts for IL-13 in the airway epithelium itself

are sparse but are more easily detectable in submucosal tissue or in sputum cells.¹⁶⁶ Thus the cellular source of the IL-13 is the cells in the submucosa or in the supramucosal mucus layer. These IL-13–producing cells comprise mainly CD4⁺ T cells, but ILC2 cells and mast cells likely contribute as well. IL-13 has many effects on airway epithelial cells.¹³⁰ Genes upregulated include eotaxins (especially eotaxin-3, also called CCL26), CCL17 (TARC), and stem cell factor, which provide chemotactic or survival signals for eosinophils, CD4⁺ Th2 cells, and mast cells, respectively. Also upregulated are *inducible nitric oxide synthase* (iNOS), periostin, and some mucin genes. iNOS catalyzes the production of NO from L-arginine, and exhaled NO can therefore be used as a biomarker of IL-13 activation of the airway epithelium.¹⁷⁹ Because iNOS is a steroid-sensitive gene, exhaled NO levels are typically low in asthmatic patients taking corticosteroid medications.¹⁸⁰ Periostin is a secreted protein of the fascilin family that interacts with integrins, TGF- β , and matrix proteins to initiate a variety of biologic effects including cell proliferation and migration, Treg cell regulation, and modulation of the biomechanical properties of collagen.¹⁸¹ Although periostin gene expression is high in airway epithelial cells, periostin protein does not immunolocalize to airway epithelial cells, because it is rapidly secreted in a basal direction.¹⁸¹ This rapid secretion from epithelial cells explains why periostin immunolocalizes to the subepithelial matrix, where it is proposed to bind and stiffen collagen.¹⁸¹ In this location, periostin is also accessible to the systemic circulation via the subepithelial bronchial venous plexus. Periostin is therefore a useful blood-based biomarker of airway epithelial cell activation by IL-13.¹⁸² The biologic consequence of periostin upregulation in asthma is uncertain. Although *in vitro* studies show that periostin potently upregulates TGF- β in epithelial

cells to induce *epithelial mesenchymal transition* (EMT),¹⁸¹ there is little evidence that EMT takes place in vivo in asthma. Mice deficient in periostin have exaggerated responses to inhaled allergen, suggesting that periostin has protective functions in the airway, perhaps through its regulation of TGF- β and Treg cell function.¹⁸³ Multiple other proteins in the airway epithelium are dysregulated by IL-13, including mucin genes.^{166,184} An overarching principle, though, is that, although epithelial-derived cytokines such as IL-33 are important for initiating and perhaps perpetuating asthma, activation of epithelial cells by IL-13 is an important amplification mechanism in the pathophysiology of asthma (see Fig. 41-5).

Eosinophils

An increase in the number of eosinophils in the airway is a pathologic hallmark of asthma.¹⁸⁵ Peripheral blood eosinophilia is frequent as well.¹⁸⁶ Airway eosinophilia is associated with worse measures of lung function, including airway hyperresponsiveness.¹⁸⁷ Drugs that suppress airway eosinophilia, including corticosteroids, anti-IgE, and anti-IL-5, are all consistently effective in reducing asthma exacerbation rates.¹⁸⁸⁻¹⁹¹ Eosinophils are thought to alter lung function in asthma via the activity of potent cytoplasmic granule proteins and through their capacity to secrete cytokines. Eosinophil granule proteins include *major basic protein* (MBP), *eosinophil cationic protein* (ECP), *eosinophil peroxidase* (EPX), and *eosinophil-derived neurotoxin* (EDN).¹⁸⁵ MBP is cytotoxic against helminths and can disrupt the integrity of lipid bilayers in mammalian cells.¹⁹² It is also an antagonist of the airway M2 muscarinic receptors that normally provide negative feedback to limit neurotransmission and bronchoconstriction.¹⁹³ ECP and EDN have ribonuclease activities that mediate neurotoxic effects, and both proteins have antiviral activity¹⁹²; EPX is a peroxidase that generates reactive oxidants and radical species.¹⁹² The overall effects of eosinophil granule proteins could be to promote nerve-mediated bronchoconstriction and activate epithelial cells. The role of eosinophil cytokines, which include TGF- α and TGF- β , may be to mediate mechanisms of airway mucin secretion and fibrosis, respectively.¹⁹⁴

Mast Cells

Mast cells have long been known to be central effector cells in asthma with multiple studies showing increases in mast cells in the airway mucosa and in airway secretions.¹⁹⁵⁻¹⁹⁷ The importance of the mast cell has been emphasized again recently by data from microarray studies in asthma and better understanding of IL-33/ST2 biology. Specifically, microarray studies in airway epithelial brushings show that mast cell genes are among the most highly upregulated genes in asthma.¹⁷⁸ Immunolocalization studies confirm increased numbers of epithelial mast cells in asthma, characterized by high expression of tryptase and carboxypeptidase A3 and low expression of chymase.¹⁹⁷ Other studies have emphasized the immunolocalization of mast cells to the submucosal airway smooth muscle, where they may contribute to airway smooth muscle hyperplasia and hyperresponsiveness.¹⁹⁸ Mast cells constitutively express multiple cell surface receptors, including Fc ϵ RI and ST2. Cross-linking of Fc ϵ RI by IgE-antigen complexes leads to mast cell degranulation and release of multiple preformed and newly

generated mediators. These IgE-mediated degranulation events are well known. ST2-mediated mast cell activation is less well appreciated but probably also important in the pathogenesis of asthma. Specifically, IL-33 binds ST2 on mast cells to enhance mast cell survival and provide a stimulus for secretion of IL-6, IL-8, and IL-13.¹⁹⁹ IL-33-mediated activation of mast cells may be of particular importance in the pathophysiology of asthma exacerbations when IL-33 is released from epithelial cells as an alarmin. Indeed, mast cells may be a cellular source of the high levels of IL-6 and IL-8 detectable in airway secretions in acute severe asthma.^{200,201}

Basophils

Basophils are circulating granulocytes that respond to allergic stimuli by migrating and accumulating at sites of allergic inflammation.^{202,203} They contain cytoplasmic granules with similar histamine levels per cell as mast cells. In contrast, the amount of tryptase in basophils is less than 1% of that in mast cells.²⁰³ Cross-linking of the Fc ϵ RI by IgE-antigen complexes causes basophil degranulation and mediator release, particularly of histamine. In addition, epithelial cell cytokines, including IL-33 and TSLP, bind to ST2 or TSLPR on basophils to cause cytokine secretion, particularly of IL-4.²⁰⁴ Recently, a role for basophils in type 2 immune responses is being explored.²⁰⁵ For example, in a mouse model of eosinophilic esophagitis, basophils are required for eosinophilic and Th2 cytokine responses.²⁰⁶ Similar information about a central role for basophils in asthma is currently lacking.

Macrophages

Macrophages are abundant in the lung and they adopt different phenotypes on the basis of signals they encounter. Exposure to IFN- γ , TNF- α , or lipopolysaccharide drives differentiation of macrophages to a classically activated (M1) phenotype.²⁰⁷ This phenotype has important roles in host defense against intracellular pathogens. Although M1 macrophages have been implicated in nonatopic asthma and in some subtypes of severe asthma, alternatively activated (M2) macrophages are more usually associated with asthma. Type 2 immune responses drive lung macrophages toward an M2 phenotype that is characterized by upregulated expression of mannose receptors and transglutaminase 2 in man and mice and by upregulated expression of arginase-1, chitinase-3-like protein-3 (also known as Ym1), and resistin-like molecule- α (also known as FIZZ1) in mice only.²⁰⁸ Markers expressed by M2 macrophages have been found in asthma in some studies²⁰⁹ but not in others.²¹⁰ Overall, airway macrophages have capacity to secrete a wide array of inflammatory mediators, but their role in asthma pathogenesis remains uncertain.

PRODUCTS OF ARACHIDONIC ACID METABOLISM—LEUKOTRIENES, PROSTAGLANDINS, AND LIPOXINS

The *cysteinyl leukotrienes* (cys-LTs) are peptide-conjugated arachidonic acid-derived inflammatory mediators that are generated by eosinophils, basophils, mast cells, macrophages, and myeloid dendritic cells.²¹¹ Cys-LTs are generated in the lipid bilayer of the cell membrane when

arachidonic acid is oxidized by 5-lipoxygenase in successive enzymatic conversions to generate *leukotriene C₄* (LTC₄), LTD₄, and LTE₄.²¹¹ Cys-LTs activate at least two receptors on smooth muscle cells to induce muscle contraction and on endothelial cells to increase vascular permeability. Medications targeting this pathway include zileuton (a 5-lipoxygenase inhibitor) and montelukast and zafirlukast (selective antagonists of cys-LT₁ receptor) and are effective in asthma, especially in patients with aspirin sensitivity and Samter triad (aspirin sensitivity, nasal polyps, and asthma).²¹² When these patients ingest cyclooxygenase-1 inhibitors, such as aspirin or other *nonsteroidal anti-inflammatory drugs* (NSAIDs), arachidonic acid metabolism is diverted away from prostanoid metabolites of arachidonate and toward excessive generation of cys-LTs. Consequently, urinary LTE₄ levels are especially high in aspirin-sensitive patients.²¹³

Prostaglandins are generated by metabolism of arachidonic acid by prostaglandin synthase enzymes and cyclooxygenase. *Prostaglandin D₂* (PGD₂) is the prostanoid most relevant to asthma pathogenesis. Mast cells are the most important cellular source of PGD₂, but Th2 cells, dendritic cells, and airway epithelial cells also produce PGD₂ at relatively low levels.^{214,215} There is good evidence that PGD₂ participates in airway responses to inhaled allergen in asthmatics. Allergen challenge in asthmatic patients leads to rapid and large increases in PGD₂ in bronchoalveolar lavage fluid,²¹⁶ and PGD₂ inhalation challenge causes bronchoconstriction and airway eosinophilia.²¹⁷ PGD₂ exerts its biologic effects via three receptors—DP1/DP, TP, and CRTH2/DP2—that are expressed collectively on hematopoietic cells, dendritic cells, epithelial cells, goblet cells, endothelial cells, and platelets.²¹⁵ Small molecule inhibitors of CRTH2 are currently in clinical trials as treatments for asthma, atopic dermatitis, and allergic rhinitis.

Lipoxins (LXs) are enzyme-derived products of arachidonic acid and ω-3 fatty acids, with putative but less well-established roles in asthma. They are counter-regulatory lipid mediators that inhibit inflammation and are rapidly inactivated. Anti-inflammatory actions include inhibition of granulocyte activation and locomotion, promotion of monocyte-derived macrophage phagocytosis of apoptotic granulocytes, blockade of T lymphocyte cytokine release, and epithelial proinflammatory cytokine and chemokine release. LXA₄ also prevents prostaglandin D₂-stimulated release of IL-13 from ILC2s.

NERVES AND NERVE RECEPTORS IN ASTHMA

The lungs are highly innervated and peptidergic, cholinergic, adrenergic, and other neurogenic mediators and their receptors may modulate airway tone and airway inflammation.²¹⁸ *Adrenergic* receptor agonists and *cholinergic* receptor antagonists are mainstays of current bronchodilator therapy for asthma. The term “neurogenic inflammation” refers to the inflammatory responses caused by tachykinins that activate specific receptors as part of the *nonadrenergic noncholinergic* (NANC) system.²¹⁹ Excitatory NANC effects are mediated by release of tachykinins such as neurokinin A and substance P acting on NK₁ and NK₂ receptors. In general, NK₁ receptors mediate gland secretion, plasma extravasation, vasodilation, and leukocyte adhesion,

whereas NK₂ receptors mediate contractions of airway smooth muscle. Inhibitory NANC effects are thought to be mediated principally by vasoactive intestinal peptide and nitric oxide. Evidence for the NANC system in asthma comes from studies showing that asthmatic subjects develop bronchoconstriction after inhaling neurokinin A or substance P.²²⁰ Although an NK₁/NK₂ receptor antagonist protected against bradykinin-induced bronchoconstriction in asthmatic subjects, a selective NK₁ receptor antagonist did not protect against hypertonic saline-induced cough or bronchoconstriction.²²¹

Parasympathetic nerves innervate airway smooth muscle, and hyperresponsiveness of airway smooth muscle is a central pathophysiologic feature of asthma. However, this hyperresponsiveness is not due to increased responsiveness to muscarinic signaling in smooth muscle cells because airway smooth muscle isolated from asthmatics does not show increased sensitivity to muscarinic agonists.²²² Parasympathetic nerves also innervate submucosal glands and regulate mucin secretion from submucosal gland cells.²²³ Notably, inflammatory cells in the airway all express muscarinic receptors, so these cells may be under parasympathetic nerve control. Relevant here is the fact that nerves produce and release inflammatory mediators and can contribute to the recruitment and activation of leukocytes.²²² These leukocytes can then alter production and release of neurotransmitters from nerves. In this way, cross talk between airway nerves and leukocytes may help maintain chronic inflammation in asthma. All of this suggests that anticholinergic treatment should benefit patients with asthma and not just because of bronchodilator effects. Indeed, it is known that vagotomy decreases inflammation in the lungs of asthmatic patients and that treating patients with uncontrolled asthma with a long-acting anticholinergic drug (tiotropium bromide) improves asthma control.²²⁴

NON-TYPE 2 IMMUNE RESPONSES IN ASTHMA

So far this chapter has emphasized type 2 immune responses in asthma, and type 2 responses are indeed the immune responses typical of many patients with asthma. However, appreciation of the heterogeneous nature of asthma at both clinical and molecular levels is driving new research to uncover the disease mechanisms that operate in “Th2-low” subsets of asthma.^{225,226} For now, relatively little is known about the mechanisms of disease in these subsets of patients, but there has been interest in exploring whether some asthma subsets are driven by type 1 immune responses or by IL-17-mediated inflammatory mechanisms. The possibility that there is a subtype of asthma that is mediated by IL-17 inflammation (characterized by neutrophilia) has been of particular interest.²²⁷

IL-17 in Asthma

The IL-17 cytokine family has members designated as IL-17A through IL-17F. CD4⁺ T cells that produce IL-17 are a distinct lineage (Th17 cells), but multiple other immune cell types also produce IL-17, including invariant natural killer T cells, CD8⁺ T cells, *lymphoid tissue inducer* (LTI)-like cells, and *gamma delta T* (γδT) cells.²²⁸ Possible pathogenic roles for IL-17 cytokines in the asthmatic airway include mediation of airway hyperresponsiveness and airway

neutrophilia. Although data from mouse models show that IL-17A produced by Th17 cells contributes to allergen-induced airway hyperresponsiveness through direct effects on airway smooth muscle,²²⁹ there is only limited evidence of this mechanism in human asthma. Similarly, the evidence linking IL-17 to airway neutrophilia in asthma is limited. Ongoing clinical trials of IL-17 inhibitors in asthma should soon clarify the importance of IL-17 family members as cytokine mediators of asthma.

Neutrophils in Asthma

Neutrophils are abundant in airway secretions in both healthy and asthmatic subjects.^{187,200} Airway neutrophils are not elevated in mild or moderate asthma but are characteristically elevated in more severe asthma²³⁰ and asthma exacerbations.²⁰⁰ In addition, neutrophil numbers correlate inversely with measures of airflow in asthma.^{231,232} Whether this neutrophil association with low airflow is causal is not known, because specific neutrophil-directed treatments have not been used in asthma. Possible mechanisms by which neutrophils could lower lung function in asthma include neutrophil-mediated oxidative stress, neutrophil protease-mediated activation of airway epithelial cells, or neutrophil protease-mediated goblet cell degranulation. The proteases secreted by neutrophils include neutrophil elastase, cathepsin G, and matrix metalloproteinase, especially MMP9. Neutrophils may not always have a pathogenic role in asthma. For example, neutrophil numbers may increase markedly in the airways in acute severe asthma, where they may have a beneficial role. Specifically, it is postulated that neutrophil elastase may digest mucin polymers to promote mucus turnover, an important recovery step in acute asthma.²³³

AIRWAY AND GUT MICROBIOME IN ASTHMA

Multiple factors have increased interest in the airway and gut microbiome as drivers of altered immune responses in asthma. First, there are data in mouse models indicating that the intestinal microbiome is a key regulator of immune cell function in early life²³⁴ and data from children show that *Bacteroides fragilis* colonization at age 3 weeks is associated with increased risk of asthma.²³⁵ Second, there are epidemiologic data that children raised on farms have lower prevalence of asthma, an association thought likely to relate to farm-related microbial exposures that influence the host microbiome.²³⁶ And, third, analysis of the microbiome of airway secretions from asthmatics and controls shows that upper airway colonization in infants by *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Moraxella catarrhalis* predicts later development of asthma.²³⁷ In addition, sequencing- and microarray-based analyses of lower airway biospecimens from asthmatics show abnormalities in the composition of bacterial microbiota, especially Proteobacteria (which include *H. influenzae*, *Pseudomonas*, *Neisseria*, *Burkholderia* species, and *Enterobacteriaceae* species.²³⁷ Notably, Proteobacterial species promote neutrophilic inflammation, and there is now great interest in whether specific microbial pathogens drive specific subtypes of asthma (such as neutrophilic asthma). Studies of the airway and gut microbiome in asthma are currently in their infancy, however, and ongoing research should reveal

whether treatment with microbes can prevent asthma in some cases or if suppression of specific microbial species can improve asthma in established disease.

MECHANISMS OF ASTHMA EXACERBATION

Asthma exacerbations represent acute-on-chronic worsening of airflow obstruction that is a consequence of worsening airway smooth muscle contraction, airway wall edema, and luminal obstruction with mucus.²³⁸ The mucus pathology is especially problematic in fatal and near fatal asthma (see later). Common upper respiratory tract viruses, especially rhinoviruses, are the most common and important cause of exacerbations in both children and adults.^{239,240} Susceptibility to acute reductions in airflow in asthmatics relates to airway mucosal remodeling. Changes in the epithelium to increase mucin stores, in airway smooth muscle to render it more hyperreactive, and in blood vessels to make them leakier render many asthmatics vulnerable to exaggerated airway responses to inhaled environmental insults, such as viruses, allergens, or pollutants.²³⁸ Asthmatic airways are hyperreactive in more ways than one—concentric smooth muscle contraction from hyperresponsiveness is one element, but mucosal edema from vascular permeability and excess mucus from mucin hypersecretion are others. The efficacy of corticosteroids in preventing exacerbations likely relates to their effects in not only reducing inflammatory cell numbers (especially eosinophils) but also improving pathologic changes in goblet cells, smooth muscle cells, and blood vessels.

PATHOLOGIC CHANGES IN THE AIRWAY IN ASTHMA

Asthma is characterized by structural changes in both the epithelium and the submucosa. These changes include abnormal deposition of collagen in the subepithelium (subepithelial fibrosis) and changes in structural cells such as goblet cells, submucosal gland cells, smooth muscle cells, and blood vessel cells (Fig. 41-6).

Pathologic Changes in Epithelial Cells in Asthma

Epithelial desquamation in asthma is a feature of acute severe asthma exacerbations, but not of chronic stable asthma. Squamous metaplasia is also not usually a feature of asthma (it is more a feature of smoking-related lung disease). The main changes in epithelial cells seen in asthma are goblet cell metaplasia and hyperplasia, which has the effect of increasing the amount of gel-forming mucins that are stored in the airway epithelium.²⁴¹

Pathologic Changes in Airway Mucus in Asthma

Airway mucus is qualitatively abnormal in asthma, reflecting changes in its cellular and biochemical constituents.²⁴² For example, eosinophil numbers are increased in asthmatic sputum²⁴³ and account for the occasional presence of bipyramidal crystals (Charcot-Leyden crystals), which are composed of eosinophil lysophospholipase.²⁴⁴ Mucin glycoproteins (“mucins”) are the predominant protein in sputum, and mucin concentrations are higher than normal in asthma.²⁴⁵ Mucins in airway mucus are the protein products of two mucin genes—MUC5AC and MUC5B. The gene

Figure 41-6 Airway pathology in asthma. Photomicrograph illustrating pathologic differences in a medium-sized airway from a nonasthmatic patient (left) and a patient with asthma (right). The stain is a Movat pentachrome stain. The airways in asthma show significant structural remodeling. The epithelium in asthma shows goblet cell hyperplasia, subepithelial fibrosis, and increased smooth muscle (Sm) volume. Scale bar 100 μ m. Bm, basement membrane; Bv, blood vessel; Ep, epithelium. (From Wadsworth S, Sin D, Dorscheid D: Clinical update on the use of biomarkers of airway inflammation in the management of asthma. *J Asthma Allergy* 4:77–86, 2011.)

expression of MUC5AC is increased in airway epithelial cells in asthma, whereas the gene expression of MUC5B is decreased.^{166,246} The functional consequence of the change in relative amounts of gene transcripts for MUC5AC and MUC5B is unknown. Albumin is another prominent protein component of airway mucus in asthma,^{200,233} and its presence in mucus reflects the heightened bronchovascular permeability in asthma, especially in acute exacerbations. Increases in the concentration of plasma proteins and mucins can alter the viscoelastic properties of airway mucus in asthma, but such changes are usually much more marked in acute asthma than in chronic asthma.²³³

Subepithelial Fibrosis

Increased amounts of types I, III, and V collagen, as well as fibronectin and tenascin, are deposited immediately beneath the epithelium in asthma.^{247,248} These structural proteins differ from typical basement membrane proteins such as collagen IV and laminin, so the subepithelial fibrosis of asthma is not a thickening of the true basement membrane but rather a deposition of a layer of interstitial collagens immediately beneath it. Although the cellular source of these proteins may be the overlying epithelial cells, myofibroblasts are increased in number in asthma and are likely a more important source.²⁴⁹ Subepithelial fibrosis is most prominent in patients with eosinophilia and airway Th2 inflammation.^{166,250} Increased amounts of collagen and other matrix proteins and abnormal cross-linking of these proteins will increase the stiffness of the subepithelial matrix. A stiff matrix can influence cell growth, survival, migration, and tissue-specific differentiation,²⁵¹ so subepithelial fibrosis may cause persistent activation of overlying epithelial cells and of embedded fibroblasts and smooth

muscle cells. Clinical studies show associations with airflow obstruction and decreased airway distensibility,²⁵² but the consequences of subepithelial fibrosis for immune dysfunction in asthma are unclear. Some have speculated that fibrosis represents a secondary barrier that impedes the passage of aeroallergens into the subepithelial space.²⁵³ Still others have hypothesized that the presence of subepithelial fibrosis promotes aeroallergen sensitization.¹³³

Airway Smooth Muscle Cells

In mild to moderate asthma there is hyperplasia of *airway smooth muscle* (ASM) that is thought to be an important mechanism for bronchial hyperresponsiveness.²⁵⁴ ASM undergoes hypertrophy together with hyperplasia in more severe subtypes of asthma.²⁵⁵ These morphometric changes in ASM have been easily demonstrated. Less straightforward have been studies of inherent smooth muscle function. Although it has long been speculated that ASM cells in asthma may be inherently hypercontractile, and such a cell phenotype can be generated in vitro,²⁵⁶ it is not proven that ASM in asthma is hypercontractile. Indeed, gene expression profiling has not identified gene signatures of such a phenotype.²⁵⁴ In addition, measurements of isometric tension in ASM from asthmatic subjects have not shown consistent evidence for enhanced force generation but have shown increased shortening.²⁵⁷ Such increases in isotonic shortening could result from alterations in contractile apparatus,²⁵⁸ tissue elastance, or extracellular matrix.²⁵⁹

Blood Vessels

The number and size of bronchial blood vessels is increased in asthma, and these vessels may have an important role in regulating airway caliber because an increase in vascular volume may swell the mucosa and narrow the airway lumen.^{260,261} Many inflammatory mediators cause vasodilation, a response that may be accompanied by increased permeability at the postcapillary venule, plasma extravasation, and airway mucosal edema.

Airway Pathology in Fatal Cases of Asthma

Exacerbations of asthma can be fatal as a result of severe airflow obstruction that is characterized by severe concentric smooth muscle contractions and extensive mucus plugging of airways. These changes were described in multiple studies in the mid-20th century, which emphasized the extensive mucus plugging of airways as a key pathologic feature.²⁶² Near-fatal asthma is also frequently associated with segmental or subsegmental lung collapse because of mucus plugs. In addition, autopsy studies showed that the degrees of airway wall thickening, smooth muscle hypertrophy, and submucosal gland hypertrophy are greater in patients who die from an asthmatic attack than in patients with asthma who die from other causes.²⁶³ Eosinophils are prominent in the airways in fatal asthma, but neutrophils may also be prominent, especially in the airways of asthmatic patients who die quickly after the onset of the fatal attack.²⁶⁴ More recent studies that have used silicone to make casts of airways from fatal cases of asthma confirm and extend the earlier gross pathology studies. The silicone cast studies show dramatic loss of airways due to mucous plugs and bronchoconstriction.²⁶⁵ Both fatal asthma and nonfatal asthma cases also show severe airway surface

Figure 41-7 Silicone rubber casts of lungs from a control and a case of fatal asthma. **A**, Low-power photograph of a control cast of the superior segment of the left lower lobe from a person without asthma. The cast shows characteristic dichotomous branching pattern with smooth parallel-sided segments and complete filling to the level of respiratory bronchioles (shown in greater detail in **B**). **C**, Cast of 18-year-old female who died of asthma. The cast shows irregular segments with tapering, constrictions, and surface protrusions. The latter corresponded to ectatic mucous gland ducts on histology. Many of the segments are truncated due to airway constriction. Close-up of two truncated airways (arrowheads) seen in **C** are shown at greater detail in **D**. (From Boser SR, Park H, Perry SF, et al: Fractal geometry of airway remodeling in human asthma. *Am J Respir Crit Care Med* 172(7):817–823, 2005.)

abnormalities that correspond to smooth muscle hypertrophy, longitudinal elastic bundles, and ectatic mucous gland ducts (Fig. 41-7).

PHENOTYPING

ASTHMA HETEROGENEITY

All asthmatics manifest airflow limitation on spirometry, airway hyperresponsiveness to specific or nonspecific challenge, and symptoms that include shortness of breath, chest tightness, wheeze, and cough. Nonetheless, patients with asthma can have a great deal of heterogeneity with respect to severity of airflow limitation, symptoms, degree of reversibility, and therapeutic response. Up to 30% to 45% of asthmatics do not respond to high doses of *inhaled corticosteroids* (ICSs) with improvements in lung function.^{266,267} Furthermore, there is significant heterogeneity in asthma triggers, the frequency and severity of exacerbations, and long-term outcomes such as irreversible loss of lung function due to airway remodeling.

Several approaches have been taken to assign asthmatics to distinct subphenotypes. Degree of airway obstruction or frequency of symptoms and rescue medication use have been used for asthma classification and care,²⁶⁸ but these categories do not provide insight into molecular or cellular mechanisms. These guidelines have been instrumental in public health efforts to improve asthma education and care through the promotion of inhaled corticosteroid use, but a better appreciation of disease heterogeneity at a molecular and cellular level will be important in treating severe asthma and in the clinical application of emerging asthma therapies.

CELLULAR PHENOTYPES

Analyses of sputum, bronchoalveolar lavage, and endo-bronchial biopsy specimens from living asthmatics and postmortem samples from fatal asthma have found that the majority of asthmatics have elevated eosinophils.²⁶⁹ However, not all asthmatics have eosinophils in their sputum; noneosinophilia may be seen in up to 25% of asthmatics not on treatment and in up to 50% of those on

treatment.²⁷⁰ Noneosinophilic asthma responds poorly to ICSs.^{271,272} Furthermore, noneosinophilic asthma is seen across a range of asthma severity and, in severe asthma, has been associated with a lower FEV₁, fewer mast cells, and less subepithelial fibrosis (i.e., airway remodeling).²⁷³ These observations and others have led to a cellular classification of asthma based on induced sputum cytologic analysis, which has four categories: (1) eosinophilic, (2) neutrophilic, (3) mixed eosinophilic and neutrophilic, and (4) paucigranulocytic asthma, where there is no observable presence of inflammatory cells.^{270,274,275} Eosinophilia is most commonly seen in classic atopic asthma with allergen-mediated inflammation and, except for severe cases, generally responds to ICSs with reduced eosinophils, improved airway obstruction, and decreased symptoms.^{250,270,276,277} Neutrophilia has been noted in asthmatics with acute and chronic infection, obesity, smoking, and exposure to irritants such as pollutants²⁷⁰; in subsets of patients with severe asthma²⁷³; and during acute asthma exacerbations.²⁰⁰ Neutrophilia is also associated with reduced FEV₁, independent of eosinophils.^{232,278} Mixed neutrophilia and eosinophilia have been reported in refractory asthma. One study found that subjects with mixed neutrophilia and eosinophilia had the poorest lung function, highest frequency of daily wheeze, and highest health care utilization.²⁷⁴

CLINICAL PHENOTYPES

Asthma heterogeneity has been analyzed at the clinical level using cluster-based multivariate approaches, designed to overcome the limitations of using only one variable, such as severity of airflow obstruction or type of cellular inflammation. Halder and colleagues²⁷⁹ used a principal components analysis and clinical experience to select variables that were measured in clinical practice—age of asthma onset, gender, atopic status, body mass index, peak flow variability, induced sputum eosinophil counts, and symptom scores. They identified three distinct clusters in mild to moderate asthmatics: one with early-onset atopic asthma and eosinophilia; another with a preponderance of obesity, females, and lack of eosinophilia; and a third with mild disease and lack of airway eosinophilia. When applied to asthmatics with more severe, refractory disease (as defined by American Thoracic Society criteria²⁸⁰), the same

analysis revealed four clusters, two similar to the early-onset atopic and obese noneosinophilic clusters identified in milder asthmatics; the other two clusters had a dissociation between eosinophilia and asthma, one with early onset and symptoms in the absence of eosinophilia and the other with late onset, minimal symptoms, and marked sputum eosinophilia. These clusters were validated by their presence in an independent prospective cohort of severe asthmatics.

Moore and associates²⁸¹ studied asthma heterogeneity through multivariate clustering of subjects from the Severe Asthma Research Program in the United States, by using only spirometric measurements and clinical characteristics. This study identified five distinct clusters. Three (one of which had severe disease) had features consistent with allergic disease—early age of onset and atopy. One additional cluster was composed of an obese, female-predominant, late-onset, nonatopic group, similar to the obese, noneosinophilic cluster in the Haldar analysis. The final cluster was a second severe asthma group, predominantly women with later-onset asthma, less atopy, and poorer response to bronchodilator. Longer disease duration correlated with asthma severity and low lung function across all study subjects.

MOLECULAR PHENOTYPES (ENDOTYPES)

An alternative approach to clustering subjects with asthma is to group them on the basis of molecular pathways found to be active in individual patients. Creating subgroups based on the activity of specific cytokine pathways has the added advantage that it points to specific pharmacologic targets and biomarkers for clinical trials. Subgroups of patients who share an underlying disease biology have been named “endotypes.”

One such study analyzed the expression levels of three epithelial genes that can serve as surrogate markers of inflammation associated with Th2-cytokines, especially IL-13.¹⁶⁶ These three genes, *POSTN* (the gene coding for periostin), *CLCA1*, and *SERPINB2*, were previously identi-

fied using genome-wide profiling of airway epithelial brushing obtained at bronchoscopy.¹⁷⁸ In this study, which examined the expression of these three genes in epithelial brushings, half the subjects had elevated levels but nearly half of subjects with mild-to-moderate asthma were indistinguishable from healthy controls. Such differential expression of Th2 genes suggested that this population of asthmatics was heterogeneous; some had Th2-high inflammation and others had Th2-low inflammation. Increased expression of IL-13 and IL-5 in Th2-high subjects, as assessed by qPCR in bronchial biopsy specimens, provided further confirmation for these endotypes. In subsequent analyses, Th2-high asthma was found to have exaggerated airway hyperresponsiveness (PC₂₀ methacholine), higher serum IgE levels, and both blood and especially bronchoalveolar lavage eosinophilia.¹⁶⁶ Th2-high subjects also had increased thickness of fibrosis below the airway epithelial basement membrane, differences in the mucin genes expressed by goblet cells (increased *MUC5AC/MUC5B* ratio), and increased numbers of intra-epithelial mast cells.¹⁹⁷ Although these analyses suggest a clinically useful dichotomous classification of distinct endotypes of asthma based on degree of Th2-inflammation, the degree of Th2-inflammation present in subjects with asthma can alternatively be seen as a continuum (Fig. 41-8).

CELLULAR BIOMARKERS

Three randomized controlled trials have found that induced sputum eosinophil counts in moderate-to-severe asthmatics can be used to tailor the dose of ICSs. All three trials found a reduction in the frequency and severity of asthma exacerbations when the ICS dose was adjusted on the basis of induced sputum eosinophil counts compared with adjustment by symptoms, lung function, or rescue medication use.²⁸²⁻²⁸⁴ There was no significant difference in lung function assessed by peak expiratory flow or spirometry. Sputum eosinophilia has also guided the use of a novel, targeted asthma treatment, mepolizumab, a humanized

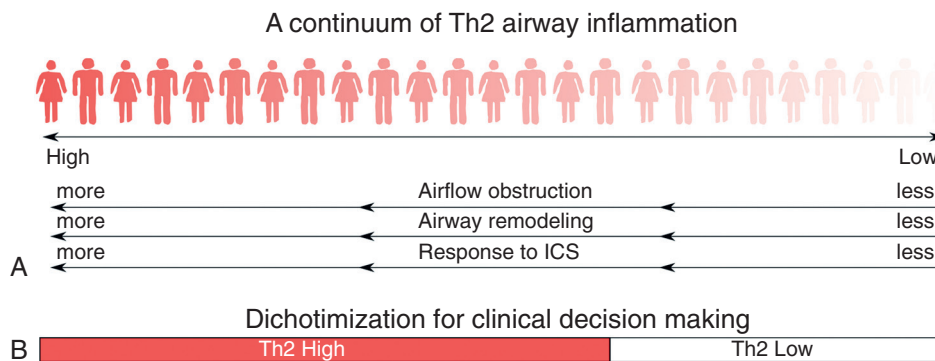

Figure 41-8 Molecular phenotypes (endotypes) in asthma. **A**, Type 2 (Th2)-driven inflammation is a dominant signal inflammatory signal in asthma. Nonetheless, among individuals, there is a continuum of Th2 inflammation, ranging from high levels of Th2 inflammation to low levels, approaching the baseline activity found in healthy controls. Higher Th2 inflammation is associated with greater airflow obstruction and airway remodeling, as well as a greater improvement in lung function with inhaled corticosteroids. The long-term temporal stability of these phenotypes is not yet known. **B**, The level of Th2 inflammation can guide the use of targeted therapies by dichotomizing individuals to either “Th2 High” or “Th2 Low” groups. A number of non-Th2 pathways in the airways have been under investigation. These additional mechanisms may explain “Th2 Low asthma” and may also coexist with Th2 inflammation across the continuum, contributing further to interindividual variation in disease. Pathways and mechanisms under investigation include Th1 inflammation, Th17 inflammation, arachidonic acid metabolism, neutrophils, obesity, intrinsic airway smooth muscle abnormalities, and abnormalities in nerves and nerve receptors.

monoclonal blocking antibody against IL-5, a key mediator in the differentiation, recruitment, and activation of eosinophils.²⁸⁵ Although early clinical trials with mepolizumab were unfavorable,^{286,287} the results of clinical studies improved when patient selection was based on the presence of eosinophils in induced sputum.^{288,289} One of these studies found a reduction in asthma exacerbations when the drug was given to subjects with refractory eosinophilic asthma, defined by sputum eosinophils greater than 3% on at least one occasion in the previous 2 years, despite high-dose ICS treatment.²⁸⁸ In another study, mepolizumab reduced the number of blood and sputum eosinophils and allowed reduction of prednisone dose.²⁸⁹ More recently, a randomized clinical trial of dupilumab, a monoclonal antibody to the α -subunit of the IL-4 receptor, showed efficacy with respect to asthma exacerbation rates in patients selected on the basis of elevated blood or sputum eosinophils.²⁹⁰

EXHALED NITRIC OXIDE AS A BIOMARKER

Measurement of the *fraction exhaled nitric oxide* (FeNO) is an alternative noninvasive biomarker of airway inflammation. FeNO levels are increased in asthma^{291,292} and are highly reproducible.²⁹³ In the setting of Th2 cytokine-driven airway inflammation, cells such as eosinophils and epithelial cells can increase NO production in part through increased transcription of inducible iNOS. Although there is a strong rationale for the use of FeNO as an asthma biomarker, the results of clinical trials that apply FeNO to guide treatment have been mixed. A randomized trial of 118 subjects with asthma did not show a difference in exacerbation frequency or total ICS used over a 1-year period when asthma treatment was based on FeNO as compared with standard guidelines.²⁹⁴ Two other studies also showed no change in exacerbation frequency, although in one, ICS dose was reduced significantly²⁹⁵ and, in the other, bronchial hyperresponsiveness improved in children.²⁹⁶ Possible reasons for the mixed performance of FeNO in these clinical studies include high sensitivity but poor specificity for eosinophilic inflammation based on the cutoff selected in specific studies,²⁹⁴ the existence of noneosinophilic asthma, and confounding by comorbidities that influence FeNO, such as nasal polyps.²⁹⁷

TH2 INFLAMMATION AS A BIOMARKER

As described earlier, the expression level of IL-13–induced genes in epithelial brushing samples allowed categorization of asthma patients into Th2-high and Th2-low endotypes.¹⁶⁶ A randomized placebo-controlled trial of ICSs in this same study showed that the Th2-low endotype did not respond to inhaled corticosteroids with an improvement in lung function, whereas the Th2-high group responded as expected. Periostin, one of the Th2 markers used in that study, is secreted basolaterally by epithelial cells,¹⁸¹ can be measured in the blood and has been used to quantify the degree of Th2 inflammation in clinical studies. Serum periostin protein levels correlated with persistent eosinophilic airway inflammation despite ICS treatment.¹⁸² This serum periostin assay was used to assess activity of the Th2 pathway and prespecify Th2 high and low subgroups in a randomized controlled trial of the anti-IL-13 monoclonal

antibody lebrikizumab in severe asthmatics.¹⁷⁹ With high serum periostin marking the Th2 high endotype, the primary outcome of improvement in FEV₁ at 12 weeks was significant only in the Th2-high group, supporting the important clinical potential of asthma endotypes in guiding the application of cytokine-based therapies for severe asthma. However, in a second randomized trial, this time performed in mild-to-moderate asthmatics who were not concurrently using ICS, treatment with lebrikizumab was not associated with clinical benefit and serum periostin levels did not identify a responsive subgroup.²⁹⁸ Whether this result represents a failure of these biomarkers to endotype patients adequately, or decreased efficacy of lebrikizumab in the absence of concomitant ICS is unclear. Finally, in a subgroup analysis within a third randomized controlled trial, elevated blood levels of periostin as well as FeNO and blood eosinophils predicted response to omalizumab, an anti-IgE monoclonal antibody.²⁹⁹ Given this mixed experience to date, additional studies will be required to define the value of blood periostin levels as a companion diagnostic in the application of Th2-targeted therapies.

NON-TH2 ASTHMA PHENOTYPES

Whether Th2-low endotypes of asthma reflect inflammatory mechanisms that are distinct from Th2 skewed inflammation or reflect non-inflammatory mechanisms is uncertain (see Fig. 41-8). Despite the focus on Th2 inflammation in mouse models of asthma and in the development of new therapies for human asthma, there is experimental evidence that both Th1- and Th17-driven inflammation can lead to airflow obstruction and exacerbate an asthma phenotype. Adoptive transfer of antigen-specific Th1 cells into ovalbumin-challenged mice led to airway hyperresponsiveness and airway inflammation that was independent of IL-13 and IL-4 in one study³⁰⁰ and dependent on IL-13 and IL-18 in another.³⁰¹ Interestingly, adoptive transfer of antigen-specific Th1 cells into antigen-challenged mice led to the development of IFN γ -dependent airway hyperresponsiveness that failed to improve with dexamethasone treatment,³⁰² suggesting a role for Th1-dependent inflammation in corticosteroid resistance. Th17 cells, on the other hand, are characterized by the secretion of IL-17A, IL-17F, IL-21, and IL-22, but not IFN- γ or IL-4.^{303,304} Most parenchymal cells, including airway epithelial cells, express receptors for Th17 cytokines including IL-17A and IL-17F, and signaling through these receptors leads to the production of pro-inflammatory factors such as IL-6, IL-1, TNF- α , and IL-8 (CXCL8, a neutrophil chemoattractant). IL-17 could contribute to the asthma phenotype by causing airway hyperresponsiveness,²²⁹ by recruiting neutrophils, and by increasing epithelial production of secreted mucins.^{305,306} In human studies, bronchoalveolar lavage samples from patients with asthma have shown increased numbers of IL-17A–producing cells,³⁰⁷ and similar findings in induced sputum also point to a positive correlation with the severity of airway hyperresponsiveness.³⁰⁸⁻³¹⁰ Furthermore, evidence of Th17 activity through identification of specific Th17 cells and IL-17A/F has also been found in human airway tissue³¹¹⁻³¹³ and peripheral blood with a positive correlation with asthma severity.^{314,315} It is also possible that Th17 inflammation contributes to corticosteroid resistance

in severe asthma, as was found in a mouse model of Th17-mediated allergic airway inflammation and hyperresponsiveness.³¹⁶ Th17-mediated inflammation may coexist with the Th2-high phenotype and augment Th2 responses.^{317,318} If there is evidence that Th1- or Th17-mediated inflammation is present in a subgroup of asthmatics, biomarkers and targeted therapeutics may be indicated. Finally, it is possible that airway inflammation does not play a dominant role in the clinical manifestations of a subset of patients with Th2-low asthma. Airway hyperresponsiveness may be the result of an abnormal airway smooth muscle response to mediators of contraction such as histamine and acetylcholine. Although a proinflammatory cytokine milieu and infiltration of smooth muscle with inflammatory cells are likely major influences on abnormal airway smooth muscle contraction, intrinsic abnormalities in the signal transduction or contractile functions of smooth muscle cells in human asthma are relatively less well studied. Because a role of airway smooth muscle hyperplasia or hypertrophy has been demonstrated in patients with asthma,^{254,319} abnormal accumulation of smooth muscle and increased airway narrowing on that basis represents another possible noninflammatory mechanism for increased airway hyperresponsiveness in asthma.

Key Points

- Asthma is common and its prevalence has been steadily increasing. In the United States, the prevalence and severity of asthma are highest in certain vulnerable populations, including children, people living below the poverty level, and specific minority groups (Puerto Ricans, black, and non-Hispanic Americans).
- Internationally, the prevalence of asthma varies dramatically, with particularly high rates in certain developed countries, including the United Kingdom, New Zealand, Australia, the United States, and Canada.
- The most common immunopathology in asthma is type 2 inflammation initiated by upstream events in the airway epithelium involving epithelial cytokines such as IL-33. The epithelial cytokines increase activity of type 2 cytokines in the airway, secreted mainly by CD4⁺ T cells, and possibly by innate lymphoid cells.

- Local type 2 cytokine secretion drives a cascade of downstream events, including IgE-mediated hypersensitivity, activation of airway epithelial cells, chemotaxis of effector cells (mast cells, eosinophils, and basophils), and remodeling of the epithelium and subepithelial matrix.
- Although asthma is defined by shared clinical characteristics such as episodic airflow limitation, chest symptoms, and airway hyperresponsiveness, asthma shows heterogeneity in other clinical characteristics including severity and response to treatment.
- The clinical heterogeneity of asthma may be explained by different underlying mechanisms. For example, type 2 inflammation is associated with greater airflow obstruction and airway remodeling. However, the degree of type 2 inflammation varies across individuals, ranging from high levels (termed “Th2-high asthma”) to low or absent levels (termed “Th2-low asthma”).
- The recognition that asthma is heterogeneous and comprises molecular phenotypes, or endotypes, is leading to the development of targeted therapies and of biomarkers that can identify those who will respond to these treatments.

INTRODUCTION

Asthma is one of the oldest known diseases, but it has only been recognized as a major public health problem since the mid-1970s. The prevalence of asthma has increased dramatically, and asthma is now recognized as a major cause of disability, medical expense, and preventable death. Asthma has attracted the full spectrum of biomedical investigation, from studies of the prevalence of asthmatic symptoms in different populations to studies of the effects of substitution of single base pairs in genes in animal models of allergic sensitization of the airways. These studies continue to refine the scientific understanding of asthma and suggest new approaches to diagnosis and treatment. The scope and depth of these studies present significant challenges in reviewing the topic of asthma. This chapter combines the perspectives of the authors with a “snapshot” of the body of knowledge, which is expanding at an explosive pace.

DEFINITION

Although asthma is a clearly recognized clinical entity, agreement on a precise definition has proved elusive. Asthma has been more often described than defined. The earliest feature described was the labored, rapid breathing typical of asthmatic attacks; the word “asthma” is derived from the ancient Greek word for “panting.” As knowledge about asthma has grown, the features described as characteristic of asthma have expanded. Measurement of maximal expiratory flow led to recognition of reversible airflow obstruction as a characteristic feature; measurement of changes in airflow after inhalation of chemical or physical irritants led to the definition of bronchial hyperresponsiveness. In addition, studies of bronchial biopsies added a description of characteristic pathologic features. This evolution in the understanding of asthma is summarized in the definition offered in the *National Heart, Lung, and Blood Institute’s* (NHLBI’s) 2007 Update on Asthma Pathophysiology and Treatment Guidelines¹:

“Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role, including mast cells, eosinophils, T lymphocytes, macrophages, neutrophils, and epithelial cells. In susceptible individuals, inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment. The inflammation also causes an associated increase in bronchial hyperresponsiveness to a variety of stimuli.”

A feature found even more consistently than eosinophilia in bronchial biopsies from patients with asthma is thickening of the *lamina reticularis* immediately underneath the subepithelial basement membrane. This thickening is considered a hallmark of airway “remodeling”; however, this feature has not yet been incorporated into consensus definitions of asthma.

The consensus conference “definition” of asthma serves well as a description of the major features of asthma but does not hold up as a precise definition. No feature is unique to asthma, and no feature is universal in patients with the condition. For example, all tests of airway caliber may be normal between attacks, even in patients whose attacks are sudden and severe. Bronchial responsiveness may be normal over most of the year in patients with seasonal asthma, and bronchial hyperresponsiveness is often found in people with allergic rhinitis but without asthma. Even the association between eosinophilic bronchial inflammation and asthma is inconstant. Some patients with recurrent episodes of wheezing and dyspnea associated with reversible airflow obstruction and bronchial hyperresponsiveness have no evidence of eosinophilic inflammation on bronchial biopsies. Other patients have eosinophilic inflammation of the bronchial mucosa and chronic cough responsive to

treatment with an inhaled corticosteroid but have neither airflow obstruction nor bronchial hyperresponsiveness. Finally, some patients with severe asthma have a predominance of neutrophils, rather than eosinophils, in their bronchial mucosa.

The lack of firm, universally agreed-upon criteria for defining asthma complicates epidemiologic studies of the prevalence of asthma in different populations and of changes in prevalence in the same population over time, but agreement on “working definitions” of asthma has led to many informative studies.

The recognition of asthma as a complex, multifactorial disorder has led to a greater focus on the individual and the varied disturbances in function that contribute to a more or less common clinical expression. Recent advances in science have not necessarily led to a more precise definition of asthma; rather, these advances have made the need for agreement on a definition seem less urgent.

CLINICAL DIAGNOSIS

The diagnosis of asthma is often made in the ambulatory care setting and is based on a careful personal history, physical examination, and lung function testing (Fig. 42-1). A number of different diseases can mimic asthma and cause some or all of the symptoms of asthma. These include vocal cord dysfunction, *chronic obstructive pulmonary disease* (COPD), cystic fibrosis, bronchiectasis, congestive heart failure, sleep apnea, pneumonia, sarcoidosis, and psychosomatic diseases and need to be considered when making the diagnosis of asthma.

PERSONAL HISTORY

Asthma can arise at any age but usually presents for the first time in childhood.² Risk factors for asthma include a family history of asthma and a personal or family history of atopy (e.g., atopic dermatitis, seasonal allergic rhinitis,

conjunctivitis).³ In addition, asthma can develop in individuals sensitive to aspirin or exposed to chemical toxins or environmental allergens.⁴

A comprehensive history is therefore critical in the assessment of the asthmatic patient. Most patients with asthma complain of intermittent symptoms of cough, shortness of breath, and/or wheezing, often described as a high-pitched musical whistling. They often experience periods of symptom-free normal breathing interrupted by periods of difficulty breathing. Asthma symptoms can last for a few minutes or days. Cough is a frequent complaint in asthma; the cough may or may not be accompanied by sputum production, may worsen at night or with activity, and/or may develop after exposure to allergens.^{5,6} Shortness of breath and wheezing, usually on exhalation, often manifest during an exacerbation and can be triggered by infection, cold air, exercise, exposure to chemical fumes or other airborne irritants, pet dander, molds, house dust mites, or other allergens.⁷ In addition, some patients describe bandlike chest tightness, or chest heaviness, during an exacerbation. Complaints of sharp stabbing or knifelike pain would be unusual in asthma and should direct the clinician to alternative diagnoses.

WORK HISTORY

Symptoms that improve on weekends and vacations and worsen at work should raise the suspicion of occupational and/or work-exacerbated asthma. Occupational asthma is new-onset asthma due to causes and conditions attributable to a particular occupational environment, whereas work-exacerbated asthma is defined as exacerbation of known asthma by the work environment.⁸ Indeed, up to 15% of all adult asthma can be attributed to occupation.^{9,10} The work exposure history should focus on identifying agents that were present at the time of asthma diagnosis or when asthma symptoms worsened. There are two major types of occupational asthma: sensitizer-induced asthma and irritant-induced asthma. Sensitizers are often further

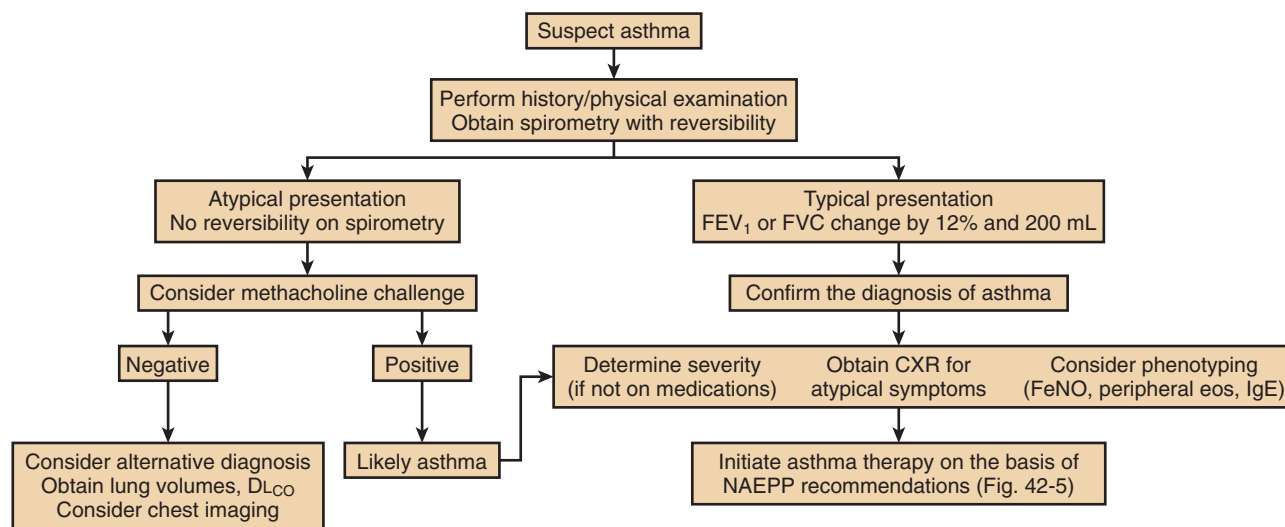

Figure 42-1 Algorithm for diagnosing asthma in adults. CXR, chest radiograph; DL_{CO}, diffusing capacity for carbon monoxide; eos, eosinophils; FeNO, fraction of exhaled nitric oxide; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; IgE, immunoglobulin E; NAEPP, National Asthma Education and Prevention Program.

classified into low-molecular-weight (small chemicals) and high-molecular-weight (usually proteins) agents.⁴ *Reactive airway dysfunction syndrome* (RADS), the best-defined form of irritant-induced asthma, results from a single high-dose exposure to irritants. (For a more detailed discussion of RADS and occupational asthma, see Chapter 72.)

PHYSICAL EXAMINATION

The physical examination should focus on the head and neck, chest, and skin. The physical examination is often normal; however, findings such as wheezing during normal breathing and/or a prolonged expiratory phase may suggest asthma. A maneuver to enhance wheezing, forced exhalation, is not specific for asthma, but suggests airway obstruction or collapse.¹¹ In addition to breathing abnormalities, subjects with asthma often have concomitant signs of associated allergic conditions and evidence of upper respiratory tract inflammation and obstruction with inflamed nasal passages and/or nasal polyps or large tonsils. The findings of eczema, hives, or atopic dermatitis on skin examination are supportive of an asthma diagnosis.^{12,12a}

PHYSIOLOGY OF AIRFLOW LIMITATION

As understanding of the pathogenesis of asthma improves and strategies for treatment evolve, it is important to recognize that the link between the pathophysiology and the treatment of asthma is functional, involving variable limitation of air flow. These two cardinal manifestations of asthma, variability of symptoms in response to environmental factors and limitation of air flow, are crucial to making the diagnosis of asthma and distinguishing asthma from other obstructive lung diseases.

During asthma exacerbations, diffuse narrowing of the airways results in profound physiologic consequences. This narrowing has been thought to take place disproportionately in the small bronchi,¹³ although more recent studies suggest a prominent role for large and medium airways.¹⁴ As a result, lung function tests are abnormal, with an increase in airway resistance and a decline in maximal expiratory flow. Airway narrowing also prevents the lungs from completely emptying (“air trapping”) due to resistance to expiratory flow and bronchial closure at higher than normal lung volumes. The breath-to-breath variability of asthmatic obstruction and air trapping led to the concept of dynamic hyperinflation.¹⁵ As a result of dynamic hyperinflation, asthmatic patients breathe at higher total lung volumes, detectable as increased residual volume.^{16,17} Despite elevated total lung volumes, asthmatics typically have reduced tidal ventilation. Decreasing *forced vital capacity* (FVC) suggests worsening air trapping, whereas worsening of the *forced expiratory volume in 1 second* (FEV₁)/FVC ratio indicates increasing airway narrowing.¹⁶

At high lung volumes, flow limitation due to bronchial narrowing is offset by increased circumferential traction on the bronchial airways due to “tethering” of airways to inflated alveoli.¹⁸ This tethering effect may be less effective in asthma because the altered mechanical properties of the extracellular matrix in asthmatic airways stiffen the airways and reduce the mechanical forces opposing *airway smooth muscle* (ASM) contraction.¹⁹ The net effect is that the work

of breathing increases significantly, due in part to decreased lung and chest wall compliance at higher thoracic volumes and in part to the greater effort required to overcome the resistance of narrowed airways. The diaphragm and intercostal muscles are overloaded due to thoracic hyperinflation and mechanically disadvantaged due to suboptimal positioning on their length-tension curves.²⁰ As a result, accessory muscles of respiration, including the abdominal muscles and the sternocleidomastoids, are required.²¹ A large proportion of the subjective dyspnea associated with asthma exacerbations has been attributed to respiratory muscle fatigue.²²

The airway obstruction and closure in asthma is nonuniform, with significant regional variability that may not be completely reflected by decreases in peak flow.^{23,24} Although pulmonary blood flow is reduced in areas of alveolar hypoventilation, the magnitude of this response is insufficient to offset more than moderate or severe airflow obstruction. Ventilation-perfusion mismatching leads to a widened alveolar-arterial oxygen difference that tracks with increasing asthma severity; the arterial oxygen tension in acute severe asthma typically falls below 70 mm Hg.^{25,26} Arterial carbon dioxide tension initially falls as alveolar ventilation increases because carbon dioxide elimination is less impaired by ventilation-perfusion mismatching than is oxygen uptake.²⁷ As respiratory muscles fatigue, carbon dioxide tension increases, so a normal or elevated PCO₂ during an asthma exacerbation suggests impending respiratory failure.²⁸ Worsening of airflow obstruction or any factor that decreases respiratory drive (such as sedation) can drop alveolar ventilation precipitously; the resultant rise in PCO₂ further inhibits respiratory drive and muscle performance and hastens respiratory failure.²⁹

PULMONARY FUNCTION TESTING

(see Chapter 25)

Even between asthma exacerbations, pulmonary function testing shows characteristic changes reflecting the reduced flow and air trapping of dynamic hyperinflation. Decreased expiratory flow can be easily and reproducibly detected with a peak flowmeter in ambulatory patients, and *peak expiratory flow* (PEF) measurement is an accepted method to correlate physiologic function with the clinical severity of asthma. However, peak flow measurements are not standardized and cannot be correlated with other measures of lung function.³⁰ PEF as a percentage of the predicted value is 10% higher than FEV₁ on average, with a great deal of variability between measurements.³¹ PEF measurements tend to underestimate less severe obstruction and overestimate more severe obstruction.³² Currently, the recommended use of PEF measurement is for the daily monitoring of ambulatory patients with difficult-to-manage asthma. In this situation, the values should be compared with an individual patient's baseline measurement obtained when asymptomatic and well controlled.^{33,34}

Spirometry

The best and most standardized test of airflow obstruction is the FEV₁. The FEV₁ has the advantage of being an objective, non-patient-reported measurement of lung function. Improvement in FEV₁ of more than 12% and 200 mL after

Figure 42-2 Flow-volume loops in asthma. **A**, The typical scooped appearance of the flow-volume loop in asthma is shown as the *solid blue line*. The predicted normal flow-volume loop is shown by the *dashed line*. **B**, The scooped appearance of the initial flow-volume loop (*blue line*) may show complete reversal following use of a bronchodilator (*brown line*). **C**, In some cases, the reversal of the scooped appearance following use of a bronchodilator is incomplete (*brown line*). (Adapted from Sameer KM: Asthma: diagnosis and management. *Med Clin North Am* 90:39–60, 2006.)

bronchodilator treatment indicates reversible airflow obstruction and is suggestive, but not diagnostic, of asthma.³⁷ Accurate measurement requires stopping *long-acting* β_2 -agonists (LABAs) for at least 12 hours and short-acting bronchodilators for at least 6 hours. Because the FEV₁ may be normal or near-normal between asthma flares, it is a poor marker of response to bronchodilators in mild asthma. The absolute value of the FEV₁ is dependent on the FVC and also reflects the small airways. Interpretation of FEV₁ therefore requires simultaneous FVC measurement. In asthma, the relative reduction in FEV₁ is typically greater than the reduction in the FVC. As a result, the FEV₁/FVC ratio in asthma is usually less than 70%. A characteristic flow-volume loop is created with scooping of the expiratory loop consistent with airflow limitation (Fig. 42-2). However, in severe asthma, this ratio may actually increase as air trapping increases residual volume and reduces the FVC. This apparent reversible restriction due to air trapping has been reported in asthma,^{16,40} but lung volumes measured by body plethysmography are usually normal or elevated.

The performance of the forced expiratory maneuver requires inhalation to total lung capacity before exhalation. In normal patients, the resultant stretch of intrapulmonary airways causes reflex bronchodilation and a shift in the pressure-volume curve. This alteration in lung mechanics is generally attributed to a transient decrease in ASM tone.⁴¹ However, some asthmatics have the opposite response, developing bronchoconstriction during deep inspiration. The mechanism of this “spirometry-induced bronchoconstriction” is unknown, but some evidence suggests that it may be partly due to increased inflammation and remodeling of asthmatic airways.⁴²

An alternative measure of airflow obstruction is the midexpiratory flow, measured between 25% and 75% of the FVC (*forced expiratory flow* [FEF]_{25%-75%}). Measured at lower lung volumes than FEV₁, reductions in the FEF_{25%-75%} may be more sensitive for identifying obstruction in small airways.⁴³ Studies in patients at high risk for asthma based on atopic symptoms have shown that this index is valuable in predicting airway hyperresponsiveness.⁴⁴ Similarly, in childhood asthmatics who have become asymptomatic, the FEF_{25%-75%} is a sensitive marker of residual physiologic abnormalities.⁴⁵ The clinical utility of the FEF_{25%-75%} is limited by the lack of acceptable standardized values.

High numbers of false-positive and false-negative results are seen when 80% of predicted FEF_{25%-75%} is used for classification.⁴⁶

The limitations of the FEF_{25%-75%} are due in part to large variation in the duration of FVC maneuvers. To address this issue, measurement of the *forced expiratory volume over the first 6 seconds* (FEV₆) has been proposed as an alternative to the FVC. The advantages of this maneuver over the FVC include ease of measurement, a more explicit end-of-test definition, and reduced risk of syncope.⁴⁷ Data are available suggesting parameters that may be used for disease classification, although the sensitivity and specificity of the FEV₁/FEV₆ in comparison with the FEV₁/FVC ratio remain controversial.^{48,49}

Lung Volumes and Diffusing Capacity

As a result of dynamic hyperinflation and consequent air trapping, residual volume, functional residual capacity, and total lung capacity may be elevated in asthma. Gas dilution techniques measure only the communicating volume of gas that equilibrates with the tracer gas during the single or multiple breath maneuvers and may underestimate these volumes due to regional heterogeneity in the distribution of ventilation.⁵⁰ For this reason, body plethysmography is often considered the method of choice for lung volume evaluation in severe asthma. However, because plethysmography measures the total volume of compressible gas within the thorax and abdomen, the inclusion of intra-abdominal gas may lead to overestimation of total lung capacity, particularly in severely obstructed asthmatics.⁵¹

Single-breath diffusing capacity is a marker of carbon monoxide gas transfer in the lungs and is reduced in most chronic lung diseases because of altered alveolar capillary volume and/or maldistribution of inspired gas due to airflow obstruction. In asthma the diffusing capacity is normal or elevated if airflow obstruction is not severe, and this finding can be useful in distinguishing asthma from other obstructive lung diseases.⁵² Elevated diffusing capacity in asthma has been attributed to increased perfusion of well-ventilated upper lung zones and is associated with large lung volumes. The unexpected finding of an increase in diffusing capacity should raise the possibility of undiagnosed asthma, whereas decreased diffusing capacity in a suspected asthmatic is suggestive of an alternate diagnosis or coexisting condition.⁵³

PROVOCATIVE CHALLENGES AND AIRWAY HYPERRESPONSIVENESS

Airway Hyperresponsiveness

Airway hyperresponsiveness (AHR) is a characteristic feature of asthma. Hyperresponsiveness can develop in response to a number of nonspecific environmental irritants, pharmacologic agonists, and inflammatory mediators. In the past, the predominant view was that airway inflammation was the mechanism causing AHR. This concept has been criticized because a number of studies have shown dissociation between AHR and inflammation,^{54,55} highlighting the fact that inflammation alone is insufficient as a mechanism of disease. Evidence suggests that a number of inflammatory *type 2 T helper* (Th2) cytokines, CD4 cells, and biochemical mediators contribute to the development of AHR in asthma. Exposure to Th2 cytokines in asthmatic airways can increase the isometric constrictor response of ASM by increasing calcium release from intracellular stores.^{56,57} In addition to the airway inflammation, factors contributing to mechanical airway obstruction have also been implicated in the pathogenesis of AHR, including epithelial permeability, smooth muscle hypertrophy, mucus hypersecretion, and airway remodeling.

AHR to environmental stimuli is a hallmark of asthma. Patients suspected of having asthma despite normal lung function testing usually develop bronchoconstriction in response to a provocative stimulus. Direct stimulation, during which a substance known to induce bronchoconstriction via direct action on smooth muscle is inhaled into the airways, is the most widely used method of assessing bronchial hyperresponsiveness. Nebulized methacholine, delivered in doubling concentrations until FEV₁ falls by more than 20%, is the agent most commonly used for bronchoprovocation. The concentration that causes a 20% fall is labeled the PC₂₀ (provocative concentration resulting in 20% fall in the FEV₁) and can be used to quantify the degree of AHR. A PC₂₀ less than 16 mg/mL is consistent with mild AHR, less than 4 mg/mL is consistent with moderate AHR, and less than 1 mg/mL with severe AHR,⁵⁸ with lower PC₂₀ levels generally corresponding to more severe asthma.⁵⁹ Bronchial hyperresponsiveness also has been associated with increased risk of developing persistent asthma and airway remodeling.⁶⁰

Indirect stimuli, such as cold air, exercise, inhalation of hypertonic saline, mannitol, and adenosine monophosphate, may also induce bronchoconstriction. Rather than working directly on smooth muscle, indirect stimuli cause the release of inflammatory mediators from airway cells that then interact with ASM to induce bronchoconstriction. Although the dose response is more difficult to assess with indirect stimuli, the results have direct applicability to daily asthma symptoms. For example, direct challenge of athletes suspected of having exercise-induced bronchoconstriction is less likely to uncover bronchoconstriction than indirect challenge using a surrogate for physical activity.⁶¹ There also may be differences between direct and indirect stimuli in the evaluation of response to treatment, with indirect challenge providing a better idea about response to therapy.⁶²

Impulse Oscillometry

Impulse oscillometry (IOS) is a form of forced oscillometry testing, a noninvasive technique to characterize the airway through the superimposition of pressure fluctuations into the airway during normal tidal breathing.⁶³ IOS delivers pressure oscillations via fixed square waves of 5- to 20-Hz frequency to measure airway resistance, the energy required to propagate a pressure wave through the airway, and reactance, the energy generated by the lungs' recoil against that pressure wave. These measurements allow calculation of the force necessary to propagate this pressure wave through the respiratory system, known as impedance. The location of airway diseases can also be localized because lower-frequency oscillations tend to travel to the lung periphery and higher-frequency ones reach only the most proximal airways.

Measurements are recorded during normal passive tidal breathing and require little training. Not surprisingly, IOS is most well studied in younger children. Significant correlations between FEV₁ and FVC by spirometry and impedance and resistance by IOS have been described.^{64,65} Most impressively, IOS has outperformed spirometry in sensitivity and specificity for the diagnosis of asthma in young children when compared to a methacholine challenge and validated clinical questionnaire.^{66,67} Despite increasing acceptance in the pediatric population, experience in adult patients remains limited.⁶⁸

IMAGING

Although traditionally, thoracic imaging has been used to rule out alternative pathologies, recent advances in imaging offer additional noninvasive techniques to support the diagnosis of asthma. The chest radiograph is most commonly normal in stable asthmatics, although nonspecific findings such as hyperinflation and bronchial wall thickening can be appreciated.⁶⁹ The primary role of the plain chest radiograph remains to rule out asthma mimics in those with atypical symptoms and to evaluate difficult-to-control symptoms.

Most commonly, chest *computed tomography* (CT) is used to evaluate chest radiographic abnormalities or identify those mimics less apparent on traditional chest radiography, such as bronchiolitis, bronchiectasis, tracheobronchomalacia, endobronchial lesions, and vascular anomalies.^{69,70} Increasingly, high-resolution chest CT techniques offer a useful tool to assess large and small airway pathology directly and indirectly. Nonspecific findings such as bronchial wall thickening, bronchial wall dilation, airway dilation, bronchiectasis, mucoid impaction, and mosaic lung attenuation consistent with air trapping are described in studies of asthmatic subjects. In a recent qualitative analysis of high-resolution CT scans of 185 severe asthma patients, abnormalities were present in 80% of the subjects with 62% demonstrating bronchial wall thickening and 40% bronchiectasis.⁷¹ Quantitative assessments of the airway tree and lung parenchyma are now possible with advances in CT technology and a number of associated proposed algorithms.⁷² Several studies have demonstrated increased large airway wall thickness in asthmatic patients

versus healthy controls regardless of disease severity.⁷³ Others support a further relationship between asthma severity and measured airway thickness.⁷⁴⁻⁷⁶ Clinical application of these techniques, however, remains limited by mostly single-center experiences and a lack of proof-of-concept studies. Despite the limited data, this is an emerging area in the diagnosis and phenotypic characterization of asthma.

Fraction of Exhaled Nitric Oxide

Nitric oxide (NO) and related compounds are generated by various resident and inflammatory airway cells and have a broad variety of functions as inflammatory mediators, vasodilators, bronchodilators, and neurotransmitters.⁷⁷ In the asthmatic airway, NO exhibits a paradoxical response by enhancing airway dilation at low concentrations but propagating inflammatory responses at higher concentrations. Eosinophilic airway inflammation, as measured by tissue-based eosinophilia, bronchoalveolar lavage eosinophilia and bronchial epithelial major basic protein density, correlates with *fraction of exhaled NO* (FeNO) in some asthma patients.

Noninvasive measurements of FeNO have been standardized for clinical use and may serve as a complementary tool in asthma diagnosis. However, the FeNO in stable, mild asthma after use of inhaled corticosteroids is often in the same range as that in normal, nonasthmatic patients.^{78,79} FeNO falls in a dose-dependent manner with steroid use, making FeNO less useful as an ongoing biomarker in patients using steroid therapy.^{80,81} A recent trial showed that an FeNO greater than 45 parts/billion excludes well-controlled asthma with a negative predictive value of nearly 90%. High FeNO suggests a severe, steroid-responsive phenotype. A decline in FeNO greater than 40% between visits is a sign of improved control, and low levels of FeNO predict lower risk of acute exacerbation.⁸² Measuring the FeNO during a period of good control can provide a baseline for comparing trends over time when following symptoms and response to treatment. The *American Thoracic Society* (ATS) has published guidelines on the use of FeNO for the diagnosis and management of asthma; however, widespread use of this technology is still lagging.⁶⁵ More recently, International ATS/*European Respiratory Society* (ERS) guidelines warned against the use of FeNO to guide treatment in severe asthma, citing low-quality evidence.⁸³

MANAGEMENT OF ASTHMA

INTRODUCTION

The inherent complexities in evaluating and treating asthma are evident from studies in the 1970s and 1980s documenting a significant number of asthma deaths that were attributable to failure of clinicians to recognize the clinical severity of asthma, thus leading to inadequate management. For example, a study of asthma deaths in the West Midland and Mersey regions of England in 1979 led to the conclusion that failure to recognize the severity of asthma delayed treatment, that routine asthma management was unsatisfactory, and that 86% of the deaths might have been preventable.⁸⁴ A similar study in 1988 included the observation that a large number of asthmatics admitted

to the hospital for observation were discharged with no escalation in the management of their asthma.⁸⁵ This ultimately led the NHLBI to convene the first expert panel to develop guidelines for the diagnosis and treatment of asthma, and the resulting recommendations were published in 1991.⁸⁶ Other guidelines soon followed, extending the NHLBI's initial recommendations. Subsequent revisions have provided clinicians with a reliable framework for evidence-based management of patients with asthma. These guidelines emphasize maintaining long-term control of symptoms through attention to environmental and social components of asthma and using treatment regimens tailored to the severity of each patient's symptoms. Crucial components of management include initial evaluation of severity (Table 42-1) and ongoing assessment of control; appropriate pharmacologic therapy to reverse bronchoconstriction and ameliorate inflammation; identification and control of environmental factors that worsen symptoms or trigger exacerbations; and creation of a partnership between the patient and the health care professional to ensure that therapy is tailored to symptoms.

ASSESSMENT

Asthma Control

The assessment of patients with asthma involves five essential steps: determining the current degree of control based on symptoms, reliever medication use, recent exacerbations, and lung function; and evaluating the risk of future adverse outcomes. With this in mind, the NHLBI updated guidelines and the *Global Initiative for Asthma* (GINA) proposed a parallel scheme for asthma control based on expert opinion³⁴ (Table 42-2). The NHLBI and GINA categorizations represent categorical interval variables with threshold values. For example, GINA guidelines accept some daytime symptoms (<2 times/week) in the definition of "controlled" asthma, whereas nocturnal symptoms move a patient to the "partially controlled" category. The importance of control indices is underscored by the relationship between poor asthma control and substantial degrees of physical impairment and diminished quality of life, even after taking the baseline severity of asthma into account.⁸⁷

Several different validated instruments exist for assessing asthma, including the Asthma Control Questionnaire (Table 42-3), Asthma Control Test (Fig. 42-3), Asthma Therapy Assessment Questionnaire (Table 42-4), and Asthma Control Scoring System (Fig. 42-4).⁸⁸⁻⁹¹ All are useful because they direct history taking, provide goals for the management of symptoms, and guide adjustments in treatment.⁹²

Lung Function

Lung function testing is an important part of assessing asthma, both for making the initial diagnosis and as a means of evaluating the response to therapy. A study from the Genetics in Asthma Network⁹³ suggested that FEV₁ and FVC are useful components of a standardized scheme for identifying the contribution of genes and environments to disease expression. Further proof of the importance of lung function testing was provided by a report that asthmatic patients with lower FEV₁ values were at significantly higher risk of needing acute care.⁹⁴ Although the FEV₁, FEV₁/FVC

Table 42-1 Classification of Severity of Asthma in Adults and Children Older Than 12 not Currently Taking Long-Term Controllers

CLASSIFICATION OF ASTHMA SEVERITY (YOUTHS ≥ 12 YR AND ADULTS)				
Components of Severity	Intermittent	PERSISTENT		
		Mild	Moderate	Severe
IMPAIRMENT				
Symptoms	≤2 days/wk	>2 days/wk but not daily	Daily	Throughout the day
Nighttime awakenings	<2×/mo	3–4×/mo	>1×/wk but not nightly	Often 7×/wk
Short-acting β ₂ -agonist use for symptom control	≤2 days/wk	>2 days/wk but not daily	Daily	Several times per day
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Lung function	Normal FEV ₁ between exacerbations <ul style="list-style-type: none">■ FEV₁ > 80% predicted■ FEV₁/FVC normal	<ul style="list-style-type: none">■ FEV₁ > 80% predicted■ FEV₁/FVC normal	<ul style="list-style-type: none">■ FEV₁ > 60% but < 80% predicted■ FEV₁/FVC reduced 5%	<ul style="list-style-type: none">■ FEV₁ < 60% predicted■ FEV₁/FVC reduced > 5%
RISK				
Exacerbations (consider frequency and severity)	0–2/yr Frequency and severity may fluctuate over time Relative annual risk of exacerbations may be related to FEV ₁	>2/yr	>2/yr	>2/yr

FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity.

Table 42-2 Classification of Asthma Control in Adults and Children Older Than 12

Components of Control	CLASSIFICATION OF ASTHMA CONTROL (YOUTHS ≥ 12 YR AND ADULTS)		
	Well Controlled	Not Well Controlled	Very Poorly Controlled
IMPAIRMENT			
Symptoms	≤2 days/wk	>2 days/wk	Throughout the day
Nighttime awakening	≤2 times/mo	1–3 times/wk	≥4 times/wk
Interference with normal activity	None	Some limitation	Extremely limited
Short-acting β-agonist use for symptom control (not prevention of EIB)	≤2 days/wk	>2 days/wk	Several times/day
FEV ₁ or peak flow	>80% predicted/personal best	60%–80% predicted/personal best	<60% predicted/personal best
Validated questionnaires			
ATAQ	0	1–2	3–4
ACQ	≤0.75*	≥1.5	N/A
ACT	≥20	16–19	≤15
RISK			
Exacerbations	0–1/yr Consider severity and interval since last exacerbation	≥2/yr [†]	
Progressive loss of lung function	Evaluation requires long-term follow-up care		
Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk		

*ACQ values of 0.76–1.4 are indeterminate regarding well-controlled asthma.

[†](1) The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's recall of previous 2–4 wk and by spirometry or peak flow measures. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit. (2) At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or intensive care unit admission) indicate poorer disease control. For treatment purposes, patients who had two or more exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.

ACQ, Asthma Control Questionnaire; ACT, Asthma Control Test; ATAQ, Asthma Therapy Assessment Questionnaire; EIB, exercise-induced bronchospasm; FEV₁, forced expiratory volume in 1 second; N/A, not applicable.

Asthma Control Test™

This survey was designed to help you describe your asthma and how your asthma affects how you feel and what you are able to do. To complete it, please mark an **X** in the one box that best describes your answer.

1. In the **past 4 weeks**, how much of the time did your **asthma** keep you from getting as much done at work, school or at home?

All of the time	Most of the time	Some of the time	A little of the time	None of the time
<input type="checkbox"/> 1	<input type="checkbox"/> 2	<input type="checkbox"/> 3	<input type="checkbox"/> 4	<input type="checkbox"/> 5

2. During the **past 4 weeks**, how often have you had shortness of breath?

More than once a day	Once a day	3 to 6 times a week	Once or twice a week	Not at all
<input type="checkbox"/> 1	<input type="checkbox"/> 2	<input type="checkbox"/> 3	<input type="checkbox"/> 4	<input type="checkbox"/> 5

3. During the **past 4 weeks**, how often did your **asthma** symptoms (wheezing, coughing, shortness of breath, chest tightness or pain) wake you up at night or earlier than usual in the morning?

4 or more nights a week	2 to 3 nights a week	Once a week	Once or Twice	Not at all
<input type="checkbox"/> 1	<input type="checkbox"/> 2	<input type="checkbox"/> 3	<input type="checkbox"/> 4	<input type="checkbox"/> 5

4. During the **past 4 weeks**, how often have you used your rescue inhaler or nebulizer medication (such as Albuterol, Ventolin®, Proventil®, or Maxair®)?

3 or more times per day	1 or 2 times per day	2 or 3 times per week	Once a week or less	Not at all
<input type="checkbox"/> 1	<input type="checkbox"/> 2	<input type="checkbox"/> 3	<input type="checkbox"/> 4	<input type="checkbox"/> 5

5. How would you rate your **asthma** control during the **past 4 weeks**?

Not Controlled at all	Poorly Controlled	Somewhat Controlled	Well Controlled	Completely Controlled
<input type="checkbox"/> 1	<input type="checkbox"/> 2	<input type="checkbox"/> 3	<input type="checkbox"/> 4	<input type="checkbox"/> 5

ratio, and PEF are useful in the diagnosis and monitoring of asthma, the utility of these measurements in improving the outcome of asthma remains incompletely defined. However, a low prebronchodilator FEV₁ is a strong predictor of decline in asthma control and a low postbronchodilator FEV₁ is a marker of future risk.^{38,39} In mild asthma, however, FEV₁ is often normal or near-normal and thus may be poorly responsive to bronchodilators.

Table 42-4 Asthma Therapy Assessment Questionnaire on Asthma Control

1. In the past 4 weeks, did you miss any work, school, or normal daily activities because of your asthma? (1 point for YES)
2. In the past 4 weeks, did you wake up at night because of your asthma? (1 point for YES)
3. Do you believe your asthma was well controlled in the past 4 weeks? (1 point for NO)
4. Do you use an inhaler for quick relief from asthma symptoms? If yes, what is the highest number of puffs in 1 day you took of this inhaler? (1 point for more than 12)
Total points—0–4, with more points indicating more control problems

PEF measurement is a standard method to correlate physiologic function with asthma severity and has been used as a marker of asthma control in many clinical trials. However, individual peak flow measurements are highly variable and the *variability* in peak flow has a greater predictive value for future exacerbations than individual PEF measurements themselves.^{35,36} The clinical usefulness of peak flow measurements is also limited by patient resistance to home monitoring and difficulty with consistently maintaining peak flow records.

Asthma Control Scoring System**Clinical assessment**

Symptoms score	25%	20%	15%	10%	5%	Total score
Diurnal symptoms	None	<4 times/w	4–7 times/w	>once/day	Severe	15
Nocturnal symptoms	None	<1 night/w	1–3 nights/w	4–7 nights/w	Severe	20
β ₂ -agonist on demand*	None	<4 doses/w	4–7 times/w	>1 dose/day	>4 doses/day	15
Physical activity	None	Very little limitation	Some limitation	Moderate limitation	Severe limitation	15
Total score						65%

Physiologic assessment

Score (%) [†]	100	80	60	40	20	Total score
FEV ₁ or PEF (% of predicted or optimal value)	>90%	80%–89%	70%–79%	60%–69%	<60%	60%
PEF variation	<10% >5 days/w	<10% >5 days/w	10%–15% >5 days/w	16%–25% >5 days/w	>25% >5 days/w	Not done

Inflammatory assessment

Score (%)	100	80	60	40	20	Total score
Airway eosinophilia (%)	0	2 or less	>2–5	5.1–8	>8	60%

* Excluding 1 dose/ day before exercise.

† Score divided by 2 if the two criteria are used.

Figure 42-4 The Asthma Control Scoring System is a means of determining the percent asthma control for a specific patient on the basis of symptoms, expiratory flows, and airway inflammation (induced-sputum eosinophilia). For each section, a percentage score is obtained. It can be added and divided by 3 to obtain a global asthma control score. The present example is about a patient who has diurnal symptoms five times a week (w), has nocturnal asthma about twice a month, uses his rescue bronchodilator almost daily, has some limitations of his activities, and has a baseline FEV₁ of 74% and 5% eosinophils in induced sputum. The global score for this patient is $65 + 60 + 60\%/3 \cong 62\%$. (From Boulet L-P, Boulet V, Milot J: How should we quantify asthma control?: a proposal. *Chest* 122(6):2217–2223, 2002.)

Biomarkers

The emergence of an increased body of literature to support the presence of asthma endotypes has made it imperative that we develop and identify biomarkers associated with each asthma type.⁹⁵⁻⁹⁷ These biomarkers will become increasingly important in determining the specific therapies that are administered to a particular patient. Currently, there are two accepted types of inflammation in asthma based on the presence or absence of Th2 inflammation: a “Th2 high” phenotype that is characterized by the presence

of peripheral eosinophilia, sputum eosinophils, elevated FeNO and/or increased markers associated with Th2 inflammation (e.g., serum periostin)⁹⁸ and a “Th2 low” phenotype characterized by the absence of any of these markers of Th2 high status. In fact, the Th2 low phenotype has no known biomarkers and this phenotype clearly requires additional study.

Before the introduction of specific biomarkers, elevated blood eosinophils were proposed as a means to identify patients with predominant Th2 inflammation. Alterations

in blood eosinophil levels are associated with response to various therapies,^{99,100} and increased eosinophils are correlated with more severe disease.^{101,102} A blood eosinophil level of greater than or equal to $0.3 \times 10^9/L$ (300 cells/ μL) has become increasingly accepted as a peripheral marker of eosinophilic inflammation. An elevated level of blood eosinophils is predictive of response to anti-IL-5 therapy.⁹⁹

High sputum eosinophil counts predict response to inhaled corticosteroids and an increased risk of future exacerbations,^{103,104} and an increase in sputum eosinophil counts following corticosteroid dose reduction predicts future deterioration of asthma control.¹⁰⁵⁻¹⁰⁷ A change of 50% in sputum eosinophil counts is considered to be a clinically significant marker of response to therapy.^{108,109} However, sputum eosinophils may be difficult to quantify in clinical practice and their current value is primarily in clinical research.

FeNO has some advantages compared with counting the number of sputum eosinophils. Measurement of FeNO can be performed rapidly in a primary care setting, requires less technical expertise, and provides real-time objective physiologic data. In particular, when accompanied by more traditional diagnostic tools, it may be used to identify eosinophilic asthma. ATS guidelines support the use of FeNO for the diagnoses of eosinophilic airway inflammation and asthma when objective evidence is necessary.⁶⁵ FeNO concentrations less than 25 ppb (<20 ppb in children) suggest that eosinophilic airway inflammation and responsiveness to corticosteroids are unlikely; elevated levels suggest eosinophilic airway inflammation and responsiveness to corticosteroids.¹¹⁰ Major limitations of using FeNO to confirm the diagnosis of asthma include the relatively high prevalence of noneosinophilic phenotypes that are characterized by a lack of increased FeNO and difficulty with clinical interpretation of values obtained in the setting of concomitant steroid use that may lead to false-negative results.^{65,77} Of note, the ATS guidelines predominantly apply to patients with mild to moderate asthma. A recent ERS/ATS task force recommended against the routine use of FeNO to diagnose asthma and to evaluate response to therapy in patients with severe disease.⁸³ However, there is still a role for FeNO in phenotyping patients by identifying those with a Th2 high/eosinophilic phenotype, regardless of asthma severity.

Serum total *immunoglobulin E* (IgE) has been used to identify patients with asthma who are likely to respond to

therapy with omalizumab, a drug that targets IgE. Omalizumab prevents IgE from binding to its receptor on the cell surface and reduces the amount of free IgE present in the blood. There are currently no commercially available assays to measure free IgE. Baseline IgE is only a modest predictor of response to omalizumab therapy.¹¹¹

Periostin is secreted by bronchial epithelial cells and fibroblasts in response to IL-4 and IL-13.^{112,113} Periostin is expressed in asthma patients and can be measured in the serum. Periostin is an emerging biomarker that offers some advantages over peripheral eosinophilia and FeNO because serum levels of periostin tend to be less variable, correlate well with tissue eosinophilia, and are not altered by treatment with steroids.⁹⁸ More importantly, serum periostin is predictive of response to therapy with biologic agents that target IL-13, making its future use as a biomarker much more promising.^{114,115} Periostin is the first biomarker in asthma to be directly correlated with the underlying pathophysiology and makes the possibility of personalizing asthma therapy more likely to be realized.¹¹⁶

The increased interest in identifying biomarkers for use in clinical practice and standardizing of biomarkers obtained in asthma clinical trials led to the convening of a task force to identify biomarkers that should be included in asthma outcomes. The task force recommended FeNO, sputum eosinophils, blood eosinophils, total IgE, allergen-specific IgE, urinary leukotriene E₄, and several new emerging markers. The emerging markers include airway imaging, exhaled breath condensate, and proteomic and genomic techniques to identify signatures in tissue obtained from patients with asthma. Although these rapid throughput methods are promising, they may be years away from clinical application.^{117,117a} The current biomarkers are summarized in Table 42-5.

ASTHMA TREATMENT APPROACHES

Overview

Current guidelines recommend adjusting therapy in a stepwise fashion to reduce daily symptoms and risk of exacerbations while minimizing the use of medications (Fig. 42-5).^{12,118} The hierarchy of treatment recommendations is based on the available literature about efficacy and safety and provides a prominent role for controller medications at all levels of asthma treatment. In general, the strategy and

Table 42-5 Asthma Biomarkers and Associated Phenotypes as Predictors of Response to Specific Therapies

Biomarker	Asthma Phenotype	Predicts
Periostin	Th2 high	Response to anti-IL-13 and IL-4 therapy ¹¹²⁻¹¹⁶
Elevated exhaled nitric oxide (>50 ppb in adults, >35 ppb in children)	Th2 high	Response to inhaled steroids ^{65,110}
Sputum eosinophils >3%	Th2 high	Response to inhaled steroids ^{103-107,109,207}
Peripheral eosinophils ($>0.3 \times 10^9/L$ or 300/ μL)	Th2 high	Response to anti-IL-5 therapy ^{99,100,292}
Elevated total IgE > 30 IU	Allergic	Response to omalizumab ^{111,202}
Allergy skin tests and elevated specific IgE	Allergic asthma with atopy	Response to immunotherapy, omalizumab
Lack of elevated peripheral and sputum eosinophils and low FeNO	Th2 low	Response to tiotropium and macrolides (likely to be poor responders to steroids) ^{215,216}

Stepwise Approach for Managing Asthma in Patients ≥ 12

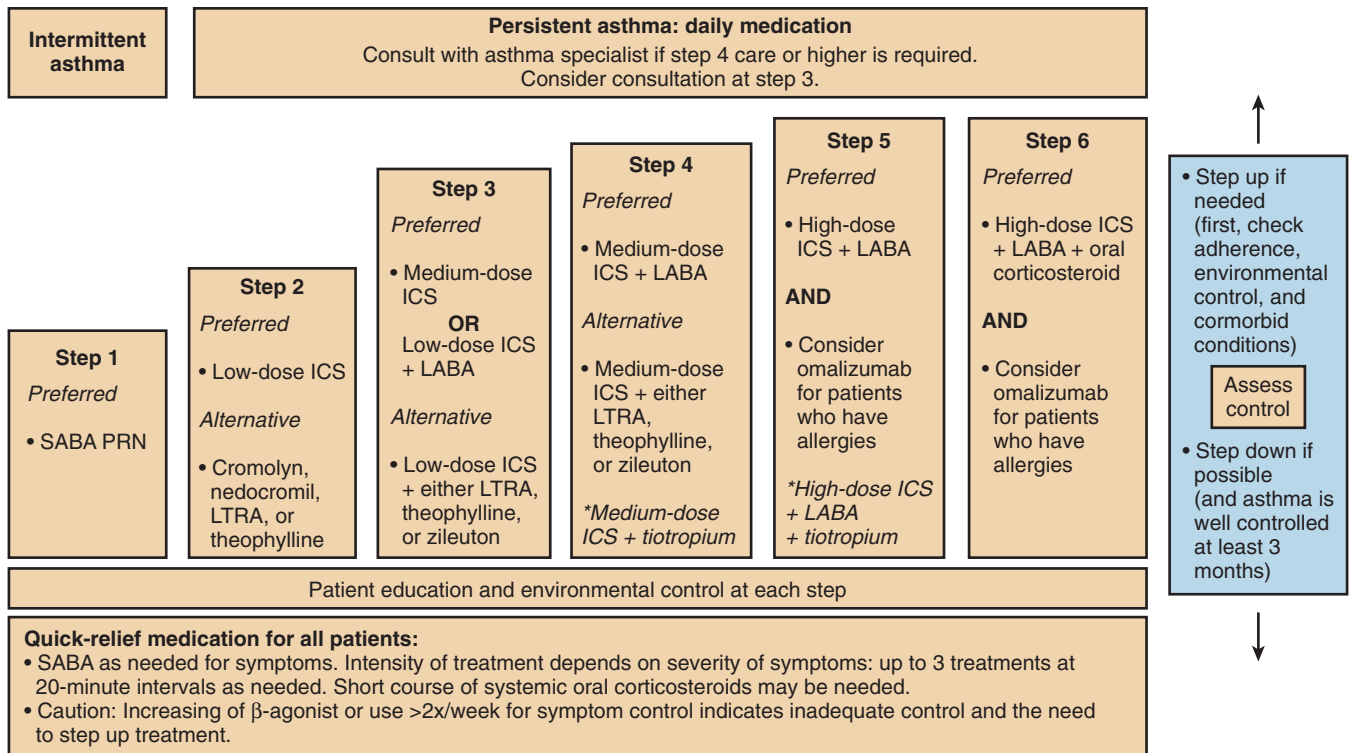

Figure 42-5 Medication recommendations for control of asthma in adults and children older than 12. SABA, short-acting β_2 -agonist; ICS, inhaled corticosteroid; LTRA, leukotriene receptor antagonist; LABA, long-acting β_2 -agonist. (Adapted from National Asthma Education and Prevention Program EPR-3 guidelines from the National Heart, Lung, and Blood Institute 2007.)

recommendations in adults and children are similar. However, the increased risk of adverse effects and/or the lack of safety data in pediatric patients for theophylline, omalizumab, and the 5-lipoxygenase inhibitor zileuton led to their exclusion from current pediatric treatment guidelines (eFigs. 42-1 and 42-2).¹¹⁸

Specific Pharmacologic Agents

β_2 -agonists. β_2 -agonists have been used for thousands of years in the form of the ephedrine-containing herbal preparation, ma huang.¹¹⁹ However, it was not until the 1940s, when the nonselective β -agonist isoproterenol was introduced, that β -agonists became the standard of care for treating airway disease. The subsequent development of the β_2 -selective agents, albuterol and terbutaline, with improved side effect profiles, led to their current role as the cornerstone of asthma therapy.¹²⁰

β_2 -agonist activity is primarily mediated by binding to a specific G-coupled transmembrane receptor found in high abundance on ASM. Receptor binding leads to increased intracellular cyclic adenosine monophosphate and relaxation of ASM.¹²¹ Notably, β_2 -receptors are also found on other resident airway cells, including airway epithelial cells and circulating immune cells, and binding to these sites may reduce vascular permeability and inflammatory mediator release.¹²² One concern raised about the chronic use of β_2 -agonists is that of receptor desensitization.¹²³ As with most signaling receptors, repeated exposure to β_2 -agonists can lead to decreased responsiveness of membrane receptors through receptor down-regulation via receptor endo-

cytosis and uncoupling of receptors from downstream transduction pathways. This response appears to be self-limited and minor in ASM.

β_2 -selective agonists are usually administered by aerosol, which maximizes delivery to target tissue (ASM), while minimizing the exposure of nontarget tissues. Both *short-acting β_2 -agonists* (SABAs) and LABAs are available, and the onset and duration of action are primarily related to lipophilicity.¹²⁴ Short-acting agents are used for rescue or emergent treatment, whereas LABAs are used in combination with inhaled corticosteroids for chronic management.

A number of highly selective SABAs are now available, and all have a rapid onset of action with peak action between 60 and 90 minutes. Because they are inhaled directly into the airways, systemic side effects are minimal, even at high doses. A β_2 -agonist preparation containing only the active enantiomer of albuterol was developed in an attempt to minimize side effects. However, clinical trials have not shown significant differences in outcome or tolerability compared with racemic albuterol.¹²⁵ On the basis of current guidelines, these medications should be used to treat symptoms not adequately controlled on a regimen of long-acting controller agents. Increased frequency of SABA use is a sign of inadequate control of symptoms or overreliance on rescue medication. Patients using more than one canister a month or requiring excessive doses of rescue inhalers (defined as > 2 doses/week) should be considered for a step-up in therapy.^{12,118}

LABAs have minimal utility for treating acute asthmatic symptoms because of their delayed onset of action. However,

in patients with inadequately controlled asthma, they can be added to an *inhaled corticosteroid* (ICS) to improve symptoms and efficacy of the ICS. Formoterol and salmeterol are the two LABAs available. Formoterol has a shorter onset of action than salmeterol, whereas salmeterol has a longer duration of action. Each has been shown to improve lung function, reduce symptoms, and reduce the frequency of exacerbations.¹²⁶

Adverse events associated with the use of β_2 -agonists are primarily due to unwanted activation of β_2 -receptors in nonpulmonary tissue. Cardiac stimulation causes tachycardia and arrhythmias, whereas skeletal muscle stimulation causes tremors and hypokalemia. Since the introduction of β -agonists, there has been concern about the clinical implications of receptor desensitization. Two unique SABAs, isoproterenol forte and fenoterol, were implicated in two “epidemics” of increased asthma deaths in the 1960s and 1970s, respectively^{127,128}; later analysis suggested that this might have been due to excessive use, rebound bronchoconstriction due to short duration of action, tachyphylaxis, or lipophilicity. After these agents were withdrawn from the market, mortality declined¹²⁹ and the safety profile of subsequent SABAs has been good. Clinical data suggest that “as-needed” versus scheduled SABA treatment is associated with improved physiology^{130,131} and fewer, less severe exacerbations.¹³²

Adverse events with LABAs have also been of concern, particularly because of their long duration of action. In the *Salmeterol Multicenter Asthma Research Trial* (SMART),¹³³ patients were randomized to salmeterol or placebo plus usual care, with approximately 13,000 patients in each arm. There was no significant difference in risk of death in either group, but subgroup analysis identified a small but increased risk of death that was more prominent in African American subjects in the salmeterol arm of the trial. However, the African American patients also had poorer control of symptoms at baseline (with more exacerbations and hospitalizations) and a lower rate of inhaled corticosteroid use than the white patients.¹³³ Importantly, the use of LABAs with inhaled corticosteroids in the same metered-dose inhaler has been shown to be safe and effective.¹³⁴

Several studies have explored the relationship between polymorphisms in the β_2 -receptor and responses to β -agonist therapy. Specifically, in patients treated with scheduled albuterol, the presence of the Arg/Arg polymorphism at the codon 16 locus (B16) was associated with lower PEF and FEV₁, and increased symptoms, more rescue inhaler use, and a higher rate of exacerbations as compared with patients who were Arg/Gly or homozygous Gly/Gly. All of these symptoms improved when regular albuterol was withdrawn.^{130,135,136} Use of LABAs (with and without inhaled corticosteroids) has been shown to worsen physiologic markers of respiratory function in Arg/Arg patients in some studies, although these findings are not consistent.^{137,138} The LARGE study demonstrated beneficial effects of LABAs in combination with ICS irrespective of B16 genotype, and the authors recommended against alterations in the current use of LABA.¹³⁹ Further research is required; however, thus far there are no indications that use of LABA in the Arg/Arg genotype is associated with undue risk. Additional genetic studies are examining potential mechanisms by which β -adrenergic receptor polymorphisms may

contribute to the risk of LABA therapy in some patients with asthma.¹⁴⁰

LABAs have modest effects on improving asthma control and reducing severe exacerbations, with an uncertain safety profile.^{141,142,142a} Despite the conflicting data on the safety of LABA therapy in certain populations, the U.S. *Food and Drug Administration* (FDA) felt that there was enough concern to warrant the addition of a black box warning on all drugs containing LABAs. The use of LABAs should be judicious, and clinicians should strive to discontinue these medications if patients no longer require them. Additionally, it is critical to prescribe LABAs only with concomitant ICSs and to warn patients about the potential dangers of LABA monotherapy. In fact, the FDA recommends the use of combination inhalers rather than two separate inhalers in order to avoid the possibility of patients using monotherapy. In 2010 the FDA mandated that manufacturers of drugs containing LABAs conduct large studies to demonstrate safety, and these studies are ongoing.¹⁴³

Other Bronchodilators. Anticholinergic agents act as bronchodilators via competition with acetylcholine at neuromuscular junctions, thereby blocking transmission of bronchoconstrictor reflexes.¹⁴⁴ The short-acting anticholinergic ipratropium bromide is effective in patients with COPD but is considered a second-line agent for treating asthma, most likely because cholinergic tone contributes less to bronchoconstriction in asthma. Although no trials have compared short-acting anticholinergics with SABAs, randomized trials studying the addition of anticholinergics to β -agonists do not show any additional benefit in patients with chronic asthma.¹⁴⁵ However, specific asthma phenotypes might be more likely to respond to anticholinergic treatment, including patients with fixed airflow obstruction, advanced age,¹⁴⁶ or longer duration of disease.¹⁴⁷ Furthermore, anticholinergics may be an acceptable alternative for certain subgroups of patients who do not tolerate β -agonist treatment or for patients with the Arg/Arg B16 genotype, although this has not been studied directly.

Tiotropium, a long-acting anticholinergic agent, has been shown to be beneficial for treating the symptoms of COPD. Spirometric improvement has been demonstrated in case series of asthmatics who do not have sputum eosinophilia¹⁴⁸ and asthmatics with concomitant COPD.¹⁴⁹ Three recent randomized controlled trials have indicated a role for tiotropium as add-on therapy to both inhaled corticosteroids and ICS/LABA combination therapy in patients with moderate to severe asthma with improved markers of airway function.¹⁵⁰⁻¹⁵² Bronchodilator responsiveness to albuterol, higher resting cholinergic tone (defined by a lower resting heart rate), and increased airway obstruction (defined by a lower FEV₁/FVC ratio) are predictors of response to tiotropium.¹⁵³ Although not yet approved for asthma, it is expected that it will be approved within the next 3 to 5 years.

Inhaled Corticosteroids. With recognition of the central role of inflammation in the pathophysiology of asthma, contemporary treatment strategies now emphasize inhaled corticosteroids for long-term control of symptoms. Corticosteroids suppress inflammatory responses through a broad influence on signal transduction and gene expression

pathways. Corticosteroids bind to a specific cytoplasmic receptor that translocates to the nucleus, where it modulates expression of inflammatory genes through inhibition of histone acetyltransferases and recruitment of histone deacetylases, two classes of histone modifiers that control DNA unwinding and gene expression epigenetically.^{154,155} Airway inflammatory cell influx and markers of airway inflammation in asthma are reduced by corticosteroid administration.^{156,157}

Systemic corticosteroids have been used in the treatment of asthma since the 1940s and continue to be a cornerstone of the management of acute exacerbations. However, systemically administered corticosteroids are associated with a variety of undesirable side effects. The introduction of ICSs in the 1970s ushered in a new era in the treatment of asthma. As with bronchodilators, delivery of drug directly into the lungs through the use of inhaled preparations minimizes systemic toxicity and improves therapeutic benefit.

The use of ICSs improves all aspects of asthma control. ICSs reduce asthmatic symptoms, improve lung function, decrease airway inflammation, and control AHR.^{158,159} A large meta-analysis showed that ICSs reduce asthma exacerbations by 55% when compared with placebo¹⁶⁰ and reduce the risk of hospitalization by 50% when compared with use of as-needed β -agonists alone.¹⁶¹ Furthermore,

risk of death from asthma is reduced in a dose-response manner with the use of ICS.¹⁶² As a result, ICSs are considered to be first-line therapy for all patients requiring more than twice-weekly β -agonist use.¹² Predictors of response to inhaled corticosteroids include FeNO level greater than 47 ppb,¹¹⁰ reversibility to albuterol and a decreased FEV1,¹⁶³ and the presence of increased sputum eosinophils (>2% to 3%).¹⁰⁰ Interestingly, a large proportion of asthma patients are persistently noneosinophilic and unlikely to respond to therapy with ICS, supporting the need for standard phenotyping of asthma with subsequent personalized therapy.^{100,164,165}

The initial recommendations regarding the use of ICS in patients with mild to moderate persistent asthma emphasized their use on a daily to twice-daily basis. Recently, there has been increased evidence that ICSs can be efficacious at reducing asthma symptoms and achieving asthma control when used intermittently in both children and adults.¹⁶⁶⁻¹⁶⁹ Despite these studies, there is still debate about the intermittent use of ICS; certainly ICS should not be used intermittently in patients with severe disease.

There are multiple different inhaled corticosteroid preparations and delivery devices on the market (Table 42-6). The inhalers differ in particle size ranging from a median mass aerodynamic diameter of about 1 micron to those with large particles that are 2 to 5 microns in size. The delivery

Table 42-6 Inhaled Steroid Preparations and Dosages

ICS Generic/Trade Names	Dosage Forms	Age	Low Daily Dose	Medium Daily Dose	High Daily Dose
Beclomethasone ■ QVAR	HFA MDI: 40 or 80 μ g/puff	5–11 ≥12	80–160 80–240	>160–320 >240–480	>320 >480

devices include dry powder inhalers and metered dose inhalers. The choice of inhaled corticosteroids is based on the physician's discretion about the patient's needs and often rests on cost, convenience of dosing, and reduction of side effects.

One key factor that warrants consideration is the role of small airway inflammation and associated obstruction as a key component of asthma pathophysiology. The presence of preserved FEV₁ with decreased mid expiratory flow and increased distal resistance is indicative of a small airway phenotype.¹⁷² Targeted therapies to help modulate small airway inflammation are important, and there are several small-particle-size inhalers that have improved deposition into the distal lung.¹⁷³ Small-particle-size inhalers include ciclesonide and beclomethasone, which has been shown to have improved deposition into the lungs.^{170,171} Utilization of these inhalers results in improvements in lung function measurements and asthma control.^{173,174} In spite of the increased evidence that small-particle-size inhalers are efficacious, superiority comparisons with large-particle-size inhalers are lacking and therefore specific recommendations to help guide clinicians on choice of ICS for any particular patient cannot be made at this time.¹⁷⁵

The risk of systemic toxicity is diminished with the use of ICS, particularly at doses less than 400 µg budesonide daily or the equivalent, but the risk is not absent. Data are conflicting about the risk of bone demineralization from ICS; although a small observational study suggested increased risk,^{176,177} a meta-analysis of several randomized controlled trials did not corroborate this finding.^{177,178} The risks of cataract formation¹⁷⁸ and glaucoma¹⁷⁹ are slightly increased, whereas hypothalamic-pituitary axis suppression, gastrointestinal bleeding, and other complications of systemic steroids are not associated with inhaled preparations. The *Towards a Revolution in COPD Health* (TORCH) trial of the use of ICS for COPD showed an increased risk of pneumonia, but this has not been demonstrated in patients with asthma.¹⁸⁰ The use of ICS in the pediatric population has raised concerns about growth suppression. However, available data show only a small and transient decrease in growth trajectory that does not translate into a reduction in adult height.^{159,164,181}

Leukotriene Modifiers. *Leukotrienes* (LTs) are derived from cell membrane arachidonic acid metabolism. LT receptors on ASM and macrophages mediate bronchoconstriction, mucus hypersecretion, and mucosal edema.¹⁸² As a result, the LT pathway is a primary target for the development of novel asthma controller medications. Commercially available *leukotriene modifiers* (LTMs) work in one of two places in the LT pathway. Zileuton inhibits the activity of 5-lipoxygenase, the enzyme that converts arachidonic acid to leukotriene A₄, which is the first step in LT synthesis. Montelukast, zafirlukast, and pranlukast are all *cysteinyl leukotriene 1* (CysLT1) *receptor antagonists* (LTRA), blocking the final step in the LT pathway. All are taken orally as either once-daily or twice-daily doses.

LTMs have a modest bronchodilator effect and may improve asthma symptoms and exacerbation rates.¹⁸³ Physiologic benefits have also been seen, with improvements in spirometry and measures of airway inflammation.¹⁸⁴ Whereas the subpopulation of patients with aspirin-

sensitive asthma may derive great benefit from LTMs,¹⁸⁵ data also suggest that LTMs are adequate as single agents in mild persistent asthma.^{186,187} Although LTMs treat multiple asthma symptoms, they are less effective than low-dose ICSs. LTMs can be used as monotherapy in exercise-induced asthma and in patients with relatively mild asthma symptoms that do not require therapy with ICS.¹⁸⁶ However, patients who require ICS for asthma control are often not candidates for LTM monotherapy. Therefore, the primary role of LTMs is as an adjunct to ICS, and the addition of LTMs typically leads to a reduction in the corticosteroid dose or an improvement in asthma control.^{188,189} Recent data suggest that the substitution of LTMs for ICS in smokers with asthma leads to similar symptomatic benefits, possibly due to impaired therapeutic responses to ICS in this population. However, it is not clear whether this benefit would persist with the addition of LTMs to ICS in patients who smoke cigarettes.¹⁹⁰ In general, LTMs are less effective than LABAs as adjunctive therapy and do not seem to confer added benefits when added to a regimen that includes an ICS and an LABA.^{191,192}

Overall, LTMs are well tolerated. Initial reports suggested a link between LTMs and eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome), but this is now thought more likely to be due to an unmasking of the syndrome by a reduction in corticosteroid dose with the introduction of an LTM.¹⁹³ Zileuton is metabolized by the cytochrome P-450 system and has been associated with reports of hepatotoxicity. As a result, liver function should be monitored during its use. The availability of a sustained-release preparation of zileuton has made it a better option as adjunctive therapy. At present, zileuton is reserved for patients with refractory asthma or who have an asthmatic phenotype suggesting benefit from the use of a leukotriene modifier.¹⁹⁴

Phosphodiesterase Inhibitors (Theophylline). Theophylline is a well-established phosphodiesterase inhibitor that has mild anti-inflammatory properties. Because of its narrow therapeutic index, theophylline is not widely used in treating asthma. However, the discovery of additional anti-inflammatory properties, likely mediated by histone deacetylation, has led to a resurgence of interest.¹⁹⁵ Although no longer a first-line therapy, theophylline is currently used in low doses as adjunctive treatment for asthma that is difficult to control with steroids alone.¹⁹⁶ The addition of theophylline to an existing drug regimen for poorly controlled asthma improves markers of control (less rescue inhaler use, better lung function) to a greater extent than LTMs.¹⁹⁰ Dose-related side effects, such as anorexia, palpitations, dysrhythmias, and seizures, require careful clinical and laboratory monitoring. Newer specific phosphodiesterase type 4 inhibitor drugs have been developed, and their safety profile is better than that of theophylline. Roflumilast has demonstrated efficacy in improving FEV₁ in asthma.^{197,198} Roflumilast is not approved for asthma but certainly has bronchodilating and anti-inflammatory properties that can be beneficial in asthma.

Targeted Biologic Agents. The introduction of omalizumab, a monoclonal antibody that binds IgE, represents a new era of therapy targeted to specific asthma phenotypes.

Omalizumab targets the receptor-binding portion of IgE, preventing it from interacting with immune cells to cause degranulation.¹⁹⁹ It must be administered subcutaneously, and the dose is based on IgE levels and body surface area. The addition of omalizumab to ICS in poorly controlled allergic asthmatics is associated with improved asthma control and fewer exacerbations.²⁰⁰ Omalizumab is generally well tolerated, but rare reports of anaphylaxis have led to recommendations that patients be observed for 2 hours after each of the first three injections to ensure safety.²⁰¹ High cost, the requirement for monitoring during treatment, and the need for careful selection of patients likely to benefit have limited the use of omalizumab. The importance of utilizing biomarkers to identify responders to omalizumab was highlighted by the EXTRA study that demonstrated significantly decreased numbers of exacerbations in subjects with high FeNO, high serum eosinophils, and elevated serum periostin in comparison with subjects with low biomarker levels.²⁰² It is critical to develop clinically applicable parameters that can guide clinician decision making about which patients should receive omalizumab for severe asthma. There is an increased degree of urgency given the cost and complexity of administering therapy with omalizumab. However, cost analysis suggests that anti-IgE therapy in patients with severe allergic asthma results in a cost-per-quality-adjusted life year that compares favorably with other uses of expensive health care resources.²⁰³ There are an increasing number of targeted biologic therapies that are currently in phase II and III trials. The early-phase studies with anti-IL-5 therapy did not demonstrate efficacy; however, this may have been due to the primary outcomes chosen and the population of patients enrolled in the these studies, underscoring the importance of identifying the correct target population for given therapies.^{204,205} Mepolizumab, a humanized monoclonal antibody to IL-5, has since demonstrated efficacy in reducing exacerbations in patients with severe asthma.^{99,206} The anti-IL-5 antibody significantly decreases eosinophil differentiation, maturation, and migration.²⁰⁷ Other biologic agents show promise for patients with severe asthma and persistent eosinophilic inflammation, including anti-IL-13 and anti-IL-4 receptor alpha antibodies.^{208,209} The emergence of new therapies for asthma holds promise for alleviating the suffering of patients with severe asthma that are failing all available therapies and experiencing untoward side effects of oral and high doses of inhaled corticosteroids.

Macrolides and Asthma. Macrolides were shown to be effective in a subset of asthma patients who had evidence of mycoplasma in their airways by polymerase chain reaction.^{210,211} These positive results generated interest in a broader use of macrolides for poorly controlled asthma. Additional randomized controlled trials demonstrated variable effects on improving asthma symptoms^{212,213} and AHR with no effect on reducing asthma control or exacerbations.²¹⁴ Recently, macrolides are reemerging as a potential therapy for patients with severe noneosinophilic or neutrophilic asthma. Two randomized controlled trials demonstrated improvements in exacerbations in patients with noneosinophilic asthma treated with macrolides; however, these outcomes were seen only in subgroup analyses.^{215,216} Therefore, the role of macrolides remains controversial,

and a recent ATS/ERS statement on severe asthma recommended against their use.⁸³ Further studies are clearly required before the controversy can be resolved.

Nonpharmacologic Treatment

Hypercontractility of ASM is believed to be a key determinant of the development of AHR in asthma. It is still unclear whether contractile force is enhanced in the asthmatic airway in which inflammatory mediators accumulate, or whether smooth muscle is abnormal in asthma. Numerous reports have identified increased ASM mass in fatal and nonfatal asthma. The cellular mechanism of increased ASM mass in asthma represents a balance between smooth muscle hypertrophy and proliferation.²¹⁷ Benayoun and associates²¹⁸ found that patients with mild asthma had larger smooth muscle cell diameter in their airways than control subjects. The increase in ASM mass correlated with asthma severity, suggesting a causal role for smooth muscle hypertrophy in the development of AHR. Conversely, Woodruff and colleagues²¹⁹ found that hyperplasia of smooth muscle is seen in mild to moderate asthma without changes in cell size or gene expression.

Current alternative nonpharmacologic treatment approaches in asthma focus on the mechanical reduction of airway smooth muscle mass in order to improve physiologic function. The application of controlled thermal energy via a radiofrequency catheter to reduce smooth muscle mass has been shown to reduce methacholine responsiveness in dogs.²²⁰ Bronchial thermoplasty is a novel intervention for asthma that is directed at the increased ASM mass. During thermoplasty, controlled thermal energy is delivered to the airway wall, thereby reducing ASM mass. In studies of thermoplasty or sham thermoplasty in patients with moderately severe asthma, thermoplasty has been shown to reduce airway responsiveness to an inhaled constrictor and to improve lung function.²²¹ Treatment leads to improvements in symptoms and quality of life and reduction in the use of rescue medication in patients with moderate or severe asthma.²²² Improvements in asthma outcomes in those receiving the sham procedure and the use of asthma quality of life as a primary outcome makes it difficult to provide strong recommendations in support of bronchial thermoplasty at this time. In addition, treatment requires a series of three bronchoscopies, exposing patients to the concomitant procedural risk. Long-term 5-year data demonstrate sustained improvements in asthma control, reduced exacerbations and decreased medication use, and a lack of evidence of long-term adverse effects.²²³ Despite this, in 2014 the ERS/ATS severe asthma guidelines recommended against the wide use of bronchial thermoplasty and suggested that this procedure should be recommended in the context of a clinical trial or in a large academic center coupled with a registry aimed at identifying predictors of response.⁸³ This recommendation was based on the perception that long-term safety data are lacking and that the procedure does not offer universal benefits to all severe asthma patients.^{223a} As for other expensive asthma therapies, it is imperative to identify responders and target this therapy to those that are most likely to benefit from the procedure.

With an increased understanding of the molecular mechanisms of asthma pathophysiology and airway

remodeling, more focused therapeutic strategies can be explored.²²⁴ In vitro studies of compounds targeting putative mediators involved in remodeling suggest a role for novel agents in the treatment of asthma.²²⁵⁻²²⁷ Recent studies highlighting novel genes associated with airway remodeling and asthmatic symptoms suggest new therapeutic avenues targeting the underlying pathogenesis of airway remodeling in asthma.²²⁸

ADDITIONAL MANAGEMENT STRATEGIES

Control of Triggers

Factors including tobacco smoke, comorbid conditions, allergen exposures, occupational exposures, pollutants, and respiratory infections have been shown to contribute to the pathogenesis and manifestations of asthma (Table 42-7). Cigarette smoking decreases asthma control and reduces the efficacy of corticosteroids. All patients with asthma who smoke cigarettes should be strongly encouraged to quit.²²⁹ Comorbid conditions, including *gastroesophageal reflux disease* (GERD) and rhinosinusitis, may worsen asthma symptoms and severity. Because treatment of GERD and sinusitis often improves the control of asthma, all difficult-to-treat patients with asthma should be evaluated for these underlying conditions.²³⁰⁻²³⁴ Reduction of allergen exposure and provision of allergen *immunotherapy* (IT) are common strategies for treating asthma. Allergic asthmatics improve when removed from their domestic environment, but environmental control is often difficult to achieve.²³⁵ The most common allergens include dust mites and cat dander. Whereas avoiding environmental allergens is ideal, most patients do not like the idea of avoiding or giving away their pets. Although overall data are mixed, several studies

have shown clinical benefits from dust mite control measures (e.g., impermeable mattress covers, frequent vacuuming, cockroach control).^{236,237} For patients with an allergic asthma phenotype, allergen-specific IT may reduce asthma symptoms and improve bronchial hyperreactivity.^{238,239} However, IT must take place under careful conditions owing to the risk of anaphylaxis, and the optimal duration of treatment is not completely clear.

Medication Adjustment Based on Asthma Control

The definition of asthma severity is based on the severity of symptoms at the time of diagnosis. More recent definitions take into account the degree of treatment necessary to maintain control and the frequency of exacerbations. Asthma control, defined as the degree of symptoms present while on appropriate therapy, is more fluid. Depending on the extent of control, a more or less aggressive approach to symptom management may be necessary. Recent studies support the importance of focusing on asthma control as a means of reducing exacerbations and morbidity.²⁴⁰ Published guidelines provide an up-to-date framework for medication choices when “stepping up” therapy to improve asthma control and “stepping down” therapy when control has been achieved (see Fig. 42-5). For patients with mild, intermittent asthma, with symptoms that return to baseline between episodes, as-needed use of a short-acting bronchodilator is usually sufficient to maintain control of symptoms. For patients with chronic asthma (symptoms > 2 times/week, nocturnal symptoms, or symptoms that affect activity), the addition of a controller medication is necessary and an ICS is the initial agent of choice.^{159,241,242} As mentioned previously, when used properly, ICSs ameliorate all asthma symptoms, improve airway physiology, and reduce hospitalizations and asthma mortality. Failure to

Table 42-7 Factors That Contribute to Worsening Asthma Control and Coexisting Conditions

Contributing Factor	Proposed Intervention
Tobacco use	<ul style="list-style-type: none"> Encourage tobacco cessation and assist with both nonpharmacologic and pharmacologic methods to help patients quit smoking
GERD	<ul style="list-style-type: none"> Consider empiric therapy for symptomatic GERD Barium swallow or pH probe study to diagnose GERD Impedance study if nonacid reflux is suspected Referral to gastroenterology for evaluation and treatment Consider surgical management for refractory cases

*May coexist with asthma with overlapping symptoms.

ENT, ear, nose, and throat specialist; GERD, gastroesophageal reflux disease.

respond to ICSs suggests nonadherence to medications, uncontrolled trigger exposures and/or comorbidities, or a steroid-nonresponsive phenotype. Approximately 30% of asthmatics fall into the latter category and demonstrate noneosinophilic inflammation and associated decreased response to conventional asthma therapy with ICS,¹⁰⁰ unlike patients with eosinophilic inflammation who demonstrate maximal response to a low dose of ICS.^{243,244} LTMs are an alternative for patients who do not tolerate or respond to ICS and are the preferred agent for patients with concomitant allergic rhinitis.^{183,184,245}

For patients with persistent asthmatic symptoms despite the appropriate use of a controller medication, clinicians have several different options for “stepping up” therapy. Some guidelines recommend the addition of a LABA to low-dose ICS (often in a combination inhaler) based on a large amount of efficacy data.²⁴⁵⁻²⁴⁸ However, because of concerns over the potential side effects of LABAs, the National Asthma Education and Prevention Program guidelines give the options of increasing the dose of ICS or adding an LABA. This is also the preferred approach for pediatric patients. Recommendations regarding up-titration of inhaled steroids have typically focused on doubling the dose of inhaled corticosteroids in patients that are not well controlled on low-dose ICS. However, there is increased recognition that doubling the dose is not efficacious at improving asthma control or lung function measurements. Furthermore, glucocorticoid resistance has been described in asthmatics that are obese.²⁴⁹⁻²⁵¹ In fact, recent studies have supported the assertion that quadrupling the dose of ICS yields improvements in asthma control and may be as effective as adding LABA therapy.²⁵² These findings will likely result in changes in future revisions of the guidelines. A third option is the addition of LTMs to low-dose ICSs.¹⁸⁹

If symptoms are still not controlled on one of the regimens just discussed, the next medication added depends on previous medication choices. For patients on increased doses of ICSs, the recommended next step is the combination of a moderate- to high-dose ICS with a LABA. However, increasing the ICS dose for a patient already on an ICS/LABA combination is less likely to be effective.^{253,254} Other options include the addition of an LTM or sustained-release theophylline to an ICS.²⁵⁵ If symptoms are not controlled on a full complement of standard medications, options include the addition of systemic corticosteroids or specific anti-IgE therapy for patients with allergic asthma.²⁰⁰

Once symptoms are controlled for a protracted period of time, therapy can be stepped down. Strategies for deescalation of therapy are determined by a patient's controller regimen. Patients on an ICS alone can be considered for a decrease in dose or dosing interval. Some data suggest that conversion to as-needed combined SABA/ICS may be effective with a lower total steroid dose.^{166,256} However, an as-needed regimen is not yet part of NHLBI guidelines. Similarly, for patients on a combined ICS/LABA or ICS/LTM regimen, clinicians should focus first on reducing the ICS component.

Assessment and Management of Concomitant Diagnoses

Vocal Cord Dysfunction. *Vocal cord dysfunction* (VCD), also referred to as paroxysmal vocal fold motion, was first

described as a separate clinical entity in 1983 and is one of the great mimics of asthma. VCD presents more often in women than in men and is common in persons 20 to 40 years old.^{257,258} It is characterized by intermittent abnormal paradoxical adduction of the true vocal cords during respiration. Patients with VCD often experience shortness of breath, neck/chest tightness, stridor, wheezing, hoarseness, frequent throat clearing, and cough. VCD patients can have normal head and neck and lung examinations or abnormal examinations with upper airway noise or stridor. Although many causes of VCD have been identified, most patients experience one of three subtypes: psychogenic VCD, irritant-associated VCD, or exercise-induced VCD.

The majority of patients with psychogenic VCD have previously been diagnosed with a psychiatric illness such as depression, anxiety, or factitious or somatoform disorder.²⁵⁹ For these patients, the vocal cords are their “stress organ” and learning how to manage stress is critical in treating their disease.

Exercise-induced VCD is often described as episodic dyspnea or shortness of breath that manifests within the first 5 minutes of exercise and resolves abruptly. These patients are frequently misdiagnosed with exercise-induced bronchospasm but fail to respond to bronchodilator therapy or steroids.²⁶⁰

Irritant-associated VCD is linked to chronic irritation of the throat resulting in vocal cord hypersensitivity. The irritants are categorized as either intrinsic (gastroesophageal reflux, laryngopharyngeal reflux, allergic rhinitis) or extrinsic (chemical or sensory irritants).

The diagnosis of VCD can be challenging because symptoms are frequently intermittent, and patients need to be symptomatic during testing. Difficulty in making the diagnosis is further complicated by the fact that up to 75% of asthmatics have coexistent VCD.^{257,261} Pulmonary function studies can reveal normal spirometry (without bronchodilator responsiveness) or an abnormal truncated inspiratory flow volume loop. Methacholine challenge has been used as a provocative measure to recreate symptoms and induce paradoxical closure of the vocal cords. Flow volume loops before and after methacholine challenge in patients with VCD often demonstrate flattening of the inspiratory curve after methacholine challenge, resulting in reversal of the MIF 50:MEF 50 (maximal inspiratory flow at 50% vital capacity-to-maximal expiratory flow at 50%) ratio from greater than 1 to less than 1.²⁶² However, specificity of these findings for VCD is limited.²⁶³ Flexible laryngoscopy and videolaryngostroboscopy are the gold standards for diagnosing VCD. Direct visualization of the cords classically demonstrates abnormal adduction of the anterior two thirds of the true vocal cords with inspiration and “chinking” of the posterior cords; the chink describes the small triangular opening that remains patent at the posterior segment of the vocal cords.²⁶⁴ The vocal cords can be seen in adduction during inspiration or during both inspiration and expiration.

Beyond treating the underlying disorder (GERD, rhinitis, and depression), there is no specific medication that treats VCD. Acute VCD can be managed with heliox to reduce airway resistance rapidly.²⁶⁵ Long term, patients are often referred to speech therapy for initiation of relaxed throat breathing exercises and diaphragmatic breathing exercises.

Although these exercises have been reported to be effective in case reports, randomized clinical trials to validate effectiveness are necessary (see Chapter 49).

Allergic Bronchopulmonary Aspergillosis. *Allergic bronchopulmonary aspergillosis* (ABPA) is a complex hypersensitivity reaction to *Aspergillus fumigatus* colonization in the airways of atopic patients.²⁶⁶ It is present in 2% to 32% of patients with asthma.²⁶⁷ Although this reaction is most commonly attributed to *A. fumigatus*, clinically identical reactions have been described for a wide variety of fungi. A more detailed description of ABPA can be found in Chapter 38. The immunopathogenesis remains incompletely understood, but current evidence suggests that persistent *A. fumigatus* colonization results in an exaggerated IgE- and IgG-mediated response driven by aspergillus-sensitive Th2 helper cells in the airway.²⁶⁶ This persistent and/or recurrent airway inflammation may be silent but generally presents clinically as severe or difficult to control asthma with dyspnea, cough and wheezing, bronchiectasis with abundant viscous mucus production, and even hemoptysis or recurrent pneumonias with migratory pulmonary opacities.

Diagnostic criteria for ABPA include a history of asthma, radiographic chest opacities positive skin test to *A. fumigatus* antigen, peripheral eosinophilia, precipitating antibodies against *A. fumigatus* antigen, elevated serum IgE, central bronchiectasis, and elevated IgE and/or IgG *A. fumigatus*-specific antibodies.²⁶⁶ The diagnosis often remains elusive because many patients do not fulfill all eight major diagnostic criteria, especially early in the disease course or when receiving corticosteroids. Treatment of ABPA targets acute airway inflammation and the prevention of the long-term complications of persistent airway inflammation. Glucocorticoids are the mainstay of therapy with the antifungal itraconazole or voriconazole reserved for patients with glucocorticoid-resistant disease.

MANAGEMENT OF ACUTE ASTHMA

Asthma is a common cause of emergency department visits and hospital admissions. Hospitalizations for asthma in adults remained relatively stable from 2000 to 2010 at approximately 119 per 100,000. Interestingly, pediatric admissions from asthma declined during the same period from 165 per 100,000 to 130 per 100,000.²⁶⁸ The treatment of acute asthma is based on the cornerstones of chronic asthma therapy but typically requires greater attention to patient monitoring and an escalation in the aggressiveness of asthma care.

Asthma exacerbations are characterized by increased shortness of breath, coughing, and/or chest tightness, and airflow limitation (as measured by decreased peak flow or FEV₁). Increased symptoms typically precede a detectable decrease in air flow,^{269,270} although a subset of patients are at high risk of exacerbations due to poor perception of airflow limitation. In the outpatient setting, an increased requirement for rescue inhalers, especially in a patient previously on a stable regimen, suggests an asthma flare. There is increased recognition that the pathophysiological mechanisms underlying asthma exacerbations are as heterogeneous as the underlying disease itself. Although we currently

treat all exacerbations similarly, some data suggest that targeted therapies for asthma exacerbations and the management of triggers may be warranted and have the potential to reduce the morbidity associated with our current therapies.²⁷¹ Exacerbations have a significant impact on asthma morbidity and mortality, and therefore it is imperative to decrease the rate of asthma exacerbations whenever possible.²⁷² Research studies focused on asthma exacerbations have used a variety of definitions, which makes it particularly challenging to compare studies. Given the recognition that standardization was needed, the National Institutes of Health convened a task force that defined an exacerbation as “a worsening of asthma requiring the use of systemic corticosteroids (or for patients on a stable maintenance dose, an increase in the use of systemic corticosteroids) to prevent a serious outcome.”²⁷³ Exacerbations are caused by a variety of triggers including infection, environmental exposures, and allergens, as well as nonadherence with prescribed asthma medications.

Patients with asthma exacerbations require prompt evaluation and treatment in order to limit morbidity and mortality. Goals include relief of airflow obstruction and amelioration of respiratory symptoms. Patients with milder symptoms (with peak flow decrease < 20%) may be evaluated in an outpatient setting but should be referred to an acute care facility if they fail to respond promptly to aggressive treatment with bronchodilators and systemic glucocorticoids.¹¹⁸ Conversely, certain patients are at high risk of asthma-related death and should be evaluated in the emergency department as soon as possible when their symptoms worsen. This includes patients with a history of recent exacerbation or previous near-fatal asthma, overutilization of SABAs or underutilization of ICSs, recent oral glucocorticoid use, poor compliance with asthma action plans, or concomitant psychiatric disease.²⁷⁰

In the acute care setting, the severity of an asthma exacerbation should be assessed by physical examination, including oximetry and measurement of peak expiratory flow. Use of accessory muscles, ability to complete sentences, and arterial oxygen tension should all be evaluated. Patients require close monitoring during the early stages of treatment because it may take several hours for symptoms to resolve. Chest radiography is useful if pneumothorax is suspected but does not usually provide clues as to the etiology of an exacerbation. Arterial blood gas measurement typically reflects mild hypoxemia and respiratory alkalosis; the normalization of arterial PCO₂ in the absence of significant symptomatic improvement suggests impending respiratory failure. Venous blood gases should not be relied on to follow PCO₂; whereas venous pH values generally agree with arterial values, venous PCO₂ poorly reflects arterial PCO₂.²⁷⁴ Anion gap metabolic acidosis may also be present, which is usually due to elevated lactate levels. Patients who fail to respond to albuterol administration within 30 to 60 minutes, with persistent dyspnea and peak flow less than 70% of baseline, require hospital admission.¹¹⁸

Key pharmacologic components of treatment include repeated or continuous short-acting bronchodilator administration (via nebulizer or metered-dose inhaler with a spacer) and systemic glucocorticoids.^{275,276} The combination of SABAs and ipratropium at the initiation of treatment is associated with physiologic improvements and

reduced rate of hospitalization, but the benefits do not persist after hospitalization.²⁷⁷ Systemic corticosteroids are unequivocally associated with more rapid return to baseline function and are considered the first-line therapy for acute asthma exacerbations. More importantly, the early administration of steroids is important in reducing the need for hospitalization and improving asthma symptoms.^{278,279} The initial dosing range for adult hospitalized patients is from 1.5 to 2 mg/kg of intravenous methylprednisolone or the equivalent.²⁸⁰ Oral steroids have been shown to have similar efficacy to intravenous preparations in the treatment of acute asthma exacerbations and therefore are an acceptable alternative in patients without life-threatening asthma.²⁸¹ ICSs are typically not used acutely, although data suggest that the addition of inhaled budesonide to systemic corticosteroids following an emergency department visit leads to improved symptoms and a decreased relapse rate.²⁸²⁻²⁸⁴ Intravenous magnesium sulfate, usually given as a 2-g bolus, may act as a smooth muscle relaxant and has been shown to reduce hospital admission rates.²⁸⁵ Supplemental oxygen to keep saturations above 90% helps maintain oxygen delivery to peripheral tissues and minimizes hypoxic pulmonary vasoconstriction.

Severe exacerbations of asthma are characterized by persistent reductions in PEF of less than 40% predicted with poor response to initial treatment. These patients may demonstrate progressive hypercapnia, fatigue, altered sensorium, and dysrhythmias and are at high risk for respiratory arrest. Low-level noninvasive positive-pressure ventilation without positive end-expiratory pressure has been shown to reduce the rate of hospitalization and may be considered in alert, cooperative patients who are not in immediate need of intubation.²⁸⁶ Heliox increases flow at the same pressure and may be a useful adjunct in patients with severe exacerbations that do not respond to initial emergency treatment.^{287,288}

Oral intubation and mechanical ventilation are mandatory for patients in respiratory arrest or impending respiratory arrest. Mechanical ventilation in patients with severe asthma exacerbations may be complicated by immediate postintubation worsening of gas exchange and hemodynamic instability due to increased airway and intrathoracic pressures from dynamic lung hyperinflation. Provided that the patient is adequately oxygenated, briefly decreasing the mandatory respiratory rate to allow an extended expiratory phase is often successful. Initial ventilator settings should be focused on minimizing dynamic hyperinflation by using a relatively low minute ventilation (with respiratory rate between 12 and 14/min and tidal volumes in the 6 to 8 mL/kg range), a high inspiratory flow rate, and minimal to no positive end-expiratory pressure.²⁸⁹ Aggressive sedation should be given to improve comfort and patient-ventilator synchrony. Short-term paralysis may be necessary in patients for whom ventilator synchrony cannot be achieved with sedation alone. Bronchodilator administration should be continued until airway resistance decreases (see Chapters 99 and 101).

CLINICIAN-PATIENT PARTNERSHIP

For chronic asthma, treatment should balance the best symptom control with the lowest possible dosage of medica-

tion.¹¹⁸ Effective management requires that patients form a partnership with health care providers in order to ensure an appropriate flow of information, with the patients assuming a major role in the assessment and treatment of their disease. Through collaborative effort, a guided self-management plan can be developed, allowing patients to titrate their own treatment on the basis of changes in symptoms and peak expiratory flow with some degree of independence. The use of such guided self-management reduces asthma morbidity in different patient populations and patient care settings.²⁹⁰ Interestingly, patient-guided use of asthma medications based on symptoms was superior to physician and biomarker-based adjustments to asthma therapies as reported by the Asthma Clinical Research Network,¹³¹ further highlighting the importance of actively involving patients in decisions regarding management of their asthma.

Crucial components of self-management plans include education, self-monitoring with symptoms and/or peak flow, regular review, and patient-directed self-management using a written action plan. Effective patient education is central to this approach. Better communication by health care providers translates into measurably better outcomes with no additional physician time commitment. Even for patients unable to engage in guided self-management, regular follow-up and medication review is beneficial because approximately 50% of patients on long-term therapy fail to take medications as directed at least some of the time.²⁹¹

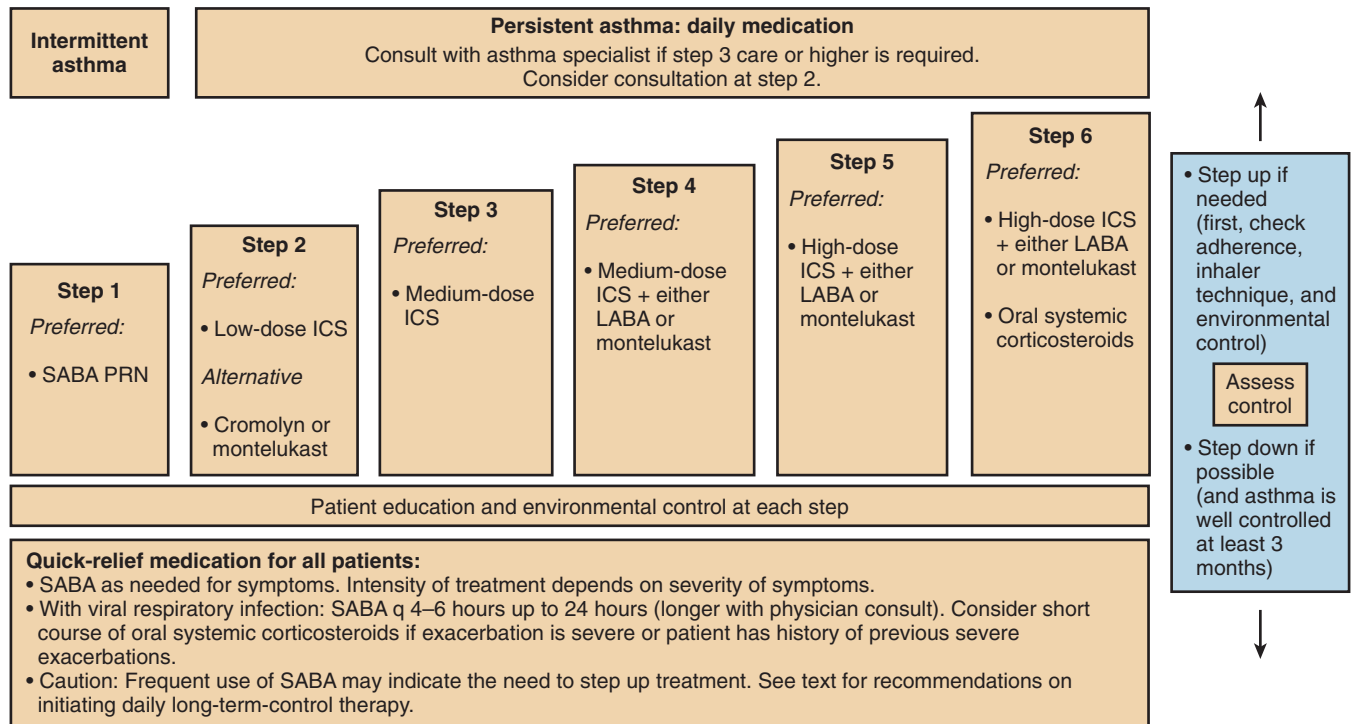

Key Points

- The approach to the diagnosis, assessment, and treatment of asthma has changed in response to the recognition that asthma is a heterogeneous disease that encompasses many phenotypes with variable responses to therapy.
- Currently, the two main phenotypes appear to be eosinophilic (Th2 high) and noneosinophilic (Th2 low) asthma. Future approaches to managing asthma will require more detailed procedures to phenotype patients in order to determine what targeted therapies will be most efficacious.
- Inhaled corticosteroids are the mainstay of asthma therapy; however, only 30% of patients have eosinophilic inflammation that is predictive of response to inhaled corticosteroids. Future studies should focus on therapies that may benefit asthmatics with noneosinophilic inflammation.
- Exhaled nitric oxide levels may be used to diagnose asthma in mild-moderate patients but should not be used to guide therapy, particularly in patients with severe asthma.
- Bronchial thermoplasty is approved for asthma treatment; however, more studies are required to determine which patients with severe persistent asthma are likely to benefit.
- Asthma education and collaboration between physicians and patients are essential in improving asthma-related outcomes.

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a condition characterized by persistent airflow limitation that is usually progressive and is associated with a chronic enhanced inflammatory response in the airways and lungs to noxious particles and gases.¹ In developed countries, cigarette smoking is the main etiologic factor, outweighing any of the other risk factors. However, in developing countries, the major cause is exposure to biomass fuels. The pathogenesis of COPD is strongly linked to the effects of cigarette smoke on the lungs. There is a general relationship between the extent of the smoking history and the severity of the airflow limitation; however, there is a huge individual variation.² Fletcher and colleagues,³ in an 8-year prospective study of working men in west London, showed that the average decline in FEV₁ in smokers is faster (60 mL/year) than in nonsmokers (30 mL/year). However, smokers who develop COPD have an average decline in FEV₁ of greater than 60 mL/year, although only a proportion of smokers develop clinically significant COPD. It is from these studies that the concept of the “susceptible smoker” developed.

The pathogenesis of COPD is generally thought to involve an abnormal inflammatory response in the lungs to the inhalation of toxic particles and gases, derived from tobacco smoke, air pollution, or occupational exposures. All smokers develop lung inflammation,⁴ but this is enhanced and fails to resolve after smoking cessation in those who develop COPD.⁵ This suggests that, in smokers who develop COPD, there is abnormal regulation of the inflammatory response in the lungs. The susceptibility factors are still poorly understood and likely involve genetic and epigenetic factors, infections, altered immune regulation, or impaired resolution of inflammation and abnormal repair mechanisms.⁶ However, the relationship between the inflammatory responses in the lungs and the accelerated decline in FEV₁, which characterizes this condition, is far from clear. More-

over, it is now well recognized that COPD is a heterogeneous condition with pathologic changes in the large and small airways (chronic bronchitis and bronchiolitis) and lung parenchyma (emphysema) that vary greatly in their expression among patients.⁷ Thus, the mechanisms resulting in these pathogenic changes are also likely to be different.

PATHOLOGIC CHANGES IN COPD

CHRONIC BRONCHITIS

Chronic bronchitis is defined in clinical terms as the presence of cough and sputum production for most days over 3 months for 2 consecutive years. This clinical definition does not include the presence of airflow limitation. It is thought to result from an innate immune response to inhaled toxic particles and gases, particularly in tobacco smoke. Inflammation is present in the epithelium of the central airways and in the mucus-producing glands in chronic bronchitis.^{4,7} This airway inflammation is associated with increased mucus production, reduced mucociliary clearance, and increased permeability of the airspace epithelial barrier.

The contribution that mucus hypersecretion makes to the airflow limitation in COPD is still uncertain. In the early stages of COPD, its contribution is small because mucus production in smokers with normal lung function does not appear to predict later development of COPD.⁸ However, in the later stages of the disease, chronic mucus hypersecretion may accelerate the loss of FEV₁ due to an increased risk of exacerbations.⁹ Chronic mucus hypersecretion may result from an inflammatory response in the submucosal glands. Inflammatory cells release serine proteases that are potent secretagogues for mucus.¹⁰ Oxidants derived from cigarette smoke and released from inflammatory leukocytes may also stimulate the overproduction of mucin by induction of the *MUC5AC* gene.¹¹

EMPHYSEMA

Emphysema is defined as enlargement of the airspaces distal to the terminal bronchioles, due to destruction of the alveolar walls (Fig. 43-1).¹² Distal airspace enlargement with alveolar destruction reduces maximal expiratory airflow by decreasing the lung elastic recoil. The centrilobular or centriacinar form of emphysema results from dilatation or destruction of the respiratory bronchioles, is the type most closely associated with tobacco smoking, and is thought to be more associated with severe small-airway obstruction.¹³ The panlobular or panacinar form of emphysema, which is associated with α_1 -antitrypsin (α_1 -AT) deficiency, results in a more even dilatation and destruction of the entire acinus. Although one or the other of these types may predominate, there is great heterogeneity. The distribution of these types of emphysema is different with an upper lobe predominance common in centrilobular emphysema

and lower lobe predominance in panlobular emphysema. The reason for this is not clear and whether different pathogenic mechanisms are involved is also unknown.

There is a relationship between the degree of emphysema and pack-years of smoking, but the relationship is not strong.⁴ Around 40% of smokers develop substantial lung destruction from emphysema, and emphysema can be found in some individuals who have normal lung function.⁴

SMALL-AIRWAY DISEASE

A major site of airflow limitation in COPD is the small conducting airways (<2 mm in diameter).¹⁴ Niewoehner and coworkers¹⁵ were the first to show that inflammation involving clusters of monocytes and macrophages could be found in the bronchioles of asymptomatic smokers who died of non-smoking-related causes out of hospital. More recent studies have shown that there are abnormalities in small

Figure 43-1 Emphysema. Paper-thin Gough-Wentworth sections prepared from whole lungs. **A**, Centriacinar emphysema in a smoker. **B**, Panacinar emphysema in α_1 -antitrypsin deficiency. The type and severity of emphysema may be difficult or impossible to determine on histopathologic grounds. **C**, Here, centriacinar emphysema is seen with dilatation of the air spaces surrounding the bronchiole. **D**, By contrast, panacinar emphysema features a more diffuse air space dilatation. (A and B, from Leslie KO, Wick MR: Practical pulmonary pathology: a diagnostic approach, ed 2. Philadelphia, 2011, Saunders; original Gough sections (C and D) prepared by T.V. Colby and the Charles B. Carrington Memorial Lung Pathology Library.)

Figure 43-2 Photomicrograph of a pulmonary artery from a patient with COPD showing prominent intimal hyperplasia and luminal narrowing. Immunostaining with antibody against α -smooth muscle actin reveals marked proliferation of smooth muscle cells in the intima. (From Rodríguez-Roisin R, Barberà JA: Pulmonary vessels. In Barnes PJ, Drazen JM, Rennard SI, Thomson NC, editors: *Asthma and COPD*, ed 2. Waltham, MA, 2008, Academic Press, Fig. 20-1.)

airways in smokers with and without COPD.¹⁶ There is also a relationship between the severity of COPD and the extent of occlusion of the airway lumen by inflammatory mucus exudates.¹⁷ Inflammation and peribronchial fibrosis contribute to the fixed airway obstruction in the small airways in COPD, and chronic inflammation, resulting in the destruction of the alveolar attachments on the outer walls of the small airways, may also contribute.

PATHOGENESIS OF COPD

PULMONARY CIRCULATION

Sustained pulmonary hypertension develops late in the course of COPD, although pathologic changes in the pulmonary vasculature with intimal hyperplasia and muscularization of small pulmonary arteries can develop in mild COPD in heavy smokers with normal lung function (Fig. 43-2). Factors that contribute to pulmonary hypertension include the following:

- Pulmonary arterial constriction as a result of hypoxia
- Endothelial dysfunction
- Remodeling (smooth muscle hypertrophy and hyperplasia) of the pulmonary arteries
- Destruction of the pulmonary capillary bed

The development of structural changes in the pulmonary arterioles leads to persistent pulmonary hypertension and right ventricular hypertrophy/enlargement and dysfunction (cor pulmonale) (see Chapter 59).

A summary of the pathologic changes in the lungs in COPD is given in Table 43-1.

An overview of the pathogenic mechanisms in COPD is given in Figure 43-3.

INFLAMMATION IN THE LUNGS OF SMOKERS WITHOUT COPD

Tobacco smoke causes airway inflammatory responses within minutes or hours of exposure.¹⁸ One of the earliest

Table 43-1 Pathologic Changes Found in COPD

PROXIMAL AIRWAYS (CARTILAGINOUS, >2-MM DIAMETER)

- ↑ Macrophages and CD8 T lymphocytes
- Few neutrophils and eosinophils (neutrophils increase with progressive disease)
- Submucosal bronchial gland enlargement and goblet cell metaplasia (results in excessive mucous production or chronic bronchitis)
- Cellular infiltrates (neutrophils and lymphocytes) of bronchial glands
- Airway epithelial squamous metaplasia, ciliary dysfunction, ↑ smooth muscle and connective tissue

PERIPHERAL AIRWAYS (NONCARTILAGINOUS, <2-MM DIAMETER)

- ↑ Macrophages and T lymphocytes (CD8 > CD4)
- ↑ B lymphocytes, lymphoid follicles and fibroblasts
- Few neutrophils or eosinophils
- Bronchiolitis at an early stage
- Luminal and inflammatory exudates
- Pathologic extension of goblet cells and squamous metaplasia into peripheral airways
- Peribronchial fibrosis and airway narrowing with progressive disease

LUNG PARENCHYMA (RESPIRATORY BRONCHIOLES AND ALVEOLI)

- ↑ Macrophages and CD8 T lymphocytes
- Alveolar wall destruction due to loss of epithelial and endothelial cells
- Development of emphysema (abnormal enlargement of airspaces distal to terminal bronchioles)
- Microscopic emphysematous changes:
 - Centrilobular (dilatation and destruction of respiratory bronchioles, commonly found in smokers and predominantly in upper zones)
 - Panacinar (destruction of the whole acinus—commonly found in α 1-antitrypsin deficiency and more common in lower zones)
- Macroscopic emphysematous changes:
 - Microscopic changes progress to bullae formation (defined as an emphysematous airspace > 1 cm in diameter)

PULMONARY VASCULATURE

- ↑ Macrophages and T lymphocytes
- Early changes:
 - Intimal thickening
 - Endothelial dysfunction
- Late changes:
 - ↑ Vascular smooth muscle
 - Collagen deposition
 - Destruction of capillary bed
 - Development of pulmonary hypertension and cor pulmonale
